Overview

C++ is a statically typed, compiled, general-purpose, case-sensitive, free-form programming language that supports procedural, object-oriented, and generic programming.

C++ is regarded as a **middle-level** language, as it comprises a combination of both high-level and low-level language features.

C++ was developed by Bjarne Stroustrup starting in 1979 at Bell Labs in Murray Hill, New Jersey, as an enhancement to the C language and originally named C with Classes but later it was renamed C++ in 1983.

C++ is a superset of C, and that virtually any legal C program is a legal C++ program.

Note: A programming language is said to use static typing when type checking is performed during compile-time as opposed to run-time.

Object-Oriented Programming

C++ fully supports object-oriented programming, including the four pillars of object-oriented development:

- Encapsulation
- Data hiding
- Inheritance
- Polymorphism

Standard Libraries

Standard C++ consists of three important parts:

- The core language giving all the building blocks including variables, data types and literals, etc.
 - The C++ Standard Library giving a rich set of functions manipulating files, strings, etc.
 - The Standard Template Library (STL) giving a rich set of methods manipulating data structures, etc.
-

The ANSI Standard

The ANSI standard is an attempt to ensure that C++ is portable -- that code you write for Microsoft's compiler will compile without errors, using a compiler on a Mac, UNIX, a Windows box, or an Alpha.

The ANSI standard has been stable for a while, and all the major C++ compiler manufacturers support the ANSI standard.

Learning C++

The most important thing to do when learning C++ is to focus on concepts and not get lost in language technical details.

The purpose of learning a programming language is to become a better programmer; that is, to become more effective at designing and implementing new systems and at maintaining old ones.

C++ supports a variety of programming styles. You can write in the style of Fortran, C, Smalltalk, etc., in any language. Each style can achieve its aims effectively while maintaining runtime and space efficiency.

Use of C++

C++ is used by hundreds of thousands of programmers in essentially every application domain.

C++ is being highly used to write device drivers and other softwares that rely on direct manipulation of hardware under realtime constraints.

C++ is widely used for teaching and research because it is clean enough for successful teaching of basic concepts.

Anyone who has used either an Apple Macintosh or a PC running Windows has indirectly used C++ because the primary user interfaces of these systems are written in C++.

Environment Setup

Before you start doing programming using C++, you need the following two softwares available on your computer.

Text Editor:

This will be used to type your program. Examples of few editors include Windows Notepad, OS Edit command, Brief, Epsilon, EMACS, and vim or vi.

Name and version of text editor can vary on different operating systems. For example, Notepad will be used on Windows and vim or vi can be used on windows as well as Linux, or UNIX.

The files you create with your editor are called source files, and for C++ they typically are named with the extension .cpp, .cp, or .c.

Before starting your programming, make sure you have one text editor in place and you have enough experience to type your C++ program.

C++ Compiler:

This is actual C++ compiler, which will be used to compile your source code into final executable program.

Most C++ compilers don't care what extension you give your source code, but if you don't specify otherwise, many will use .cpp by default

Most frequently used and free available compiler is GNU C/C++ compiler, otherwise you can have compilers either from HP or Solaris if you have respective Operating Systems.

Installing GNU C/C++ Compiler:

UNIX/Linux Installation:

If you are using **Linux** or **UNIX**, then check whether GCC is installed on your system by entering the following command from the command line:

```
$ g++-v
```

If you have installed GCC, then it should print a message such as the following:

```
Using built-in specs.  
Target: i386-redhat-linux  
Configured with: ../configure --prefix=/usr .....  
Thread model: posix  
gcc version 4.1.220080704 (RedHat 4.1.2-46)
```

If GCC is not installed, then you will have to install it yourself using the detailed instructions available at <http://gcc.gnu.org/install/>

Mac OS X Installation:

If you use Mac OS X, the easiest way to obtain GCC is to download the Xcode development environment from Apple's web site and follow the simple installation instructions.

Xcode is currently available at developer.apple.com/technologies/tools/.

Windows Installation:

To install GCC at Windows, you need to install MinGW. To install MinGW, go to the MinGW homepage, www.mingw.org, and follow the link to the MinGW download page. Download the latest version of the MinGW installation program which should be named MinGW-<version>.exe.

While installing MinGW, at a minimum, you must install gcc-core, gcc-g++, binutils, and the MinGW runtime, but you may wish to install more.

Add the bin subdirectory of your MinGW installation to your **PATH** environment variable so that you can specify these tools on the command line by their simple names.

When the installation is complete, you will be able to run gcc, g++, ar, ranlib, dlltool, and several other GNU tools from the Windows command line.

C++ Basic Syntax

W

hen we consider a C++ program, it can be defined as a collection of objects that communicate via invoking each other's methods. Let us now briefly look into what do class, object, methods and instant variables mean.

- **Object** - Objects have states and behaviors. Example: A dog has states - color, name, breed as well as behaviors - wagging, barking, eating. An object is an instance of a class.
- **Class** - A class can be defined as a template/blueprint that describes the behaviors/states that object of its type support.
- **Methods** - A method is basically a behavior. A class can contain many methods. It is in methods where the logics are written, data is manipulated and all the actions are executed.
- **Instant Variables** - Each object has its unique set of instant variables. An object's state is created by the values assigned to these instant variables.

C++ Program Structure:

Let us look at a simple code that would print the words *Hello World*.

```
#include<iostream>
using namespace std;

// main() is where program execution begins.

int main()
{
    cout << "Hello World"; // prints Hello
    World return 0;
}
```

Let us look various parts of the above program:

- The C++ language defines several headers, which contain information that is either necessary or useful to your program. For this program, the header **<iostream>** is needed.
 - The line **using namespace std;** tells the compiler to use the std namespace. Namespaces are a relatively recent addition to C++.
 - The next line **// main() is where program execution begins.** is a single-line comment available in C++. Single-line comments begin with // and stop at the end of the line.
 - The line **int main()** is the main function where program execution begins.
-

- The next line `cout << "This is my first C++ program.";` causes the message "This is my first C++ program" to be displayed on the screen.
- The next line `return 0;` terminates `main()` function and causes it to return the value 0 to the calling process.

Compile & Execute C++ Program:

Let's look at how to save the file, compile and run the program. Please follow the steps given below:

- Open a text editor and add the code as above.
- Save the file as: `hello.cpp`
- Open a command prompt and go to the directory where you saved the file.
- Type '`g++ hello.cpp`' and press enter to compile your code. If there are no errors in your code, the command prompt will take you to the next line and would generate `a.out` executable file.
- Now, type '`a.out`' to run your program.
- You will be able to see 'Hello World ' printed on the window.

```
$ g++ hello.cpp
$ ./a.out
HelloWorld
```

Make sure that `g++` is in your path and that you are running it in the directory containing file `hello.cpp`.

You can compile C/C++ programs using `makefile`. For more details, you can check [Makefile Tutorial](#).

Semicolons & Blocks in C++:

In C++, the semicolon is a statement terminator. That is, each individual statement must be ended with a semicolon. It indicates the end of one logical entity.

For example, following are three different statements:

```
x = y;
y = y+1;
add(x, y);
```

A block is a set of logically connected statements that are surrounded by opening and closing braces. For example:

```
{
    cout << "Hello World"; // prints Hello
    World return 0;
}
```

C++ does not recognize the end of the line as a terminator. For this reason, it does not matter where on a line you put a statement. For example:

```
x = y;
y = y+1;
add(x, y);
```

is the same as

```
x = y; y = y+1; add(x, y);
```

C++ Identifiers:

A C++ identifier is a name used to identify a variable, function, class, module, or any other user-defined item. An identifier starts with a letter A to Z or a to z or an underscore (_) followed by zero or more letters, underscores, and digits (0 to 9).

C++ does not allow punctuation characters such as @, \$, and % within identifiers. C++ is a case-sensitive programming language. Thus, **Manpower** and **manpower** are two different identifiers in C++.

Here are some examples of acceptable identifiers:

```
mohd      zara      abc      move_name  a_123
myname50   _temp     j        a23b9      retVal
```

C++ Keywords:

The following list shows the reserved words in C++. These reserved words may not be used as constant or variable or any other identifier names.

Asm	else	new	this
Auto	enum	operator	throw
Bool	explicit	private	true
Break	export	protected	try
Case	extern	public	typedef
Catch	false	register	typeid
Char	float	reinterpret_cast	typename
Class	for	return	union
Const	friend	short	unsigned
const_cast	goto	signed	using
continue	if	sizeof	virtual
Default	inline	Static	void
Delete	int	static_cast	volatile
Do	long	Struct	wchar_t
Double	mutable	Switch	while
dynamic_cast	namespace	Template	

Trigraphs:

A few characters have an alternative representation, called a trigraph sequence. A trigraph is a three-character sequence that represents a single character and the sequence always starts with two question marks.

Trigraphs are expanded anywhere they appear, including within string literals and character literals, in comments, and in preprocessor directives.

Following are most frequently used trigraph sequences:

Trigraph	Replacement
??=	#
??/	\
??'	^
??([
??)]
??!	
??<	{
??>	}
??-	~

All the compilers do not support trigraphs and they are not advised to be used because of their confusing nature.

Whitespace in C++:

A line containing only whitespace, possibly with a comment, is known as a blank line, and C++ compiler totally ignores it.

Whitespace is the term used in C++ to describe blanks, tabs, newline characters and comments. Whitespace separates one part of a statement from another and enables the compiler to identify where one element in a statement, such as `int`, ends and the next element begins. Therefore, in the statement,

```
int age;
```

there must be at least one whitespace character (usually a space) between `int` and `age` for the compiler to be able to distinguish them. On the other hand, in the statement,

```
fruit = apples + oranges; // Get the total fruit
```

no whitespace characters are necessary between `fruit` and `=`, or between `=` and `apples`, although you are free to include some if you wish for readability purpose.

Comments

Program comments are explanatory statements that you can include in the C++ code that you write and helps anyone reading its source code. All programming languages allow for some form of comments.

C++ supports single-line and multi-line comments. All characters available inside any comment are ignored by C++ compiler.

C++ comments start with `/*` and end with `*/`. For example:

```
/* This is a comment */

/* C++ comments can also
 * span multiple lines */
```

A comment can also start with `//`, extending to the end of the line. For example:

```
#include<iostream>
using namespace std;

main()
{
    cout << "Hello World"; // prints Hello World

    return 0;
}
```

When the above code is compiled, it will ignore **// prints Hello World** and final executable will produce the following result:

```
HelloWorld
```

Within a `/*` and `*/` comment, `//` characters have no special meaning. Within a `//` comment, `/*` and `*/` have no special meaning. Thus, you can "nest" one kind of comment within the other kind. For example:

```
/* Comment out printing of Hello World: cout
<< "Hello World"; // prints Hello World */
```

Data Types

W

hile doing programming in any programming language, you need to use various variables to store

various information. Variables are nothing but reserved memory locations to store values. This means that when you create a variable you reserve some space in memory.

You may like to store information of various data types like character, wide character, integer, floating point, double floating point, boolean, etc. Based on the data type of a variable, the operating system allocates memory and decides what can be stored in the reserved memory.

Primitive Built-in Types:

C++ offer the programmer a rich assortment of built-in as well as user defined data types. Following table lists down seven basic C++ data types:

Type	Keyword
Boolean	bool
Character	char
Integer	int
Floating point	float
Double floating point	double
Valueless	void
Wide character	wchar_t

Several of the basic types can be modified using one or more of these type modifiers:

- signed
 - unsigned
 - short
 - long
-

The following table shows the variable type, how much memory it takes to store the value in memory, and what is maximum and minimum value, which can be stored in such type of variables.

Type	Typical Bit Width	Typical Range
char	1byte	-127 to 127 or 0 to 255
unsigned char	1byte	0 to 255
signed char	1byte	-127 to 127
int	4bytes	-2147483648 to 2147483647
unsigned int	4bytes	0 to 4294967295
signed int	4bytes	-2147483648 to 2147483647
short int	2bytes	-32768 to 32767
unsigned short int	Range	0 to 65,535
signed short int	Range	-32768 to 32767
long int	4bytes	-2,147,483,647 to 2,147,483,647
signed long int	4bytes	same as long int
unsigned long int	4bytes	0 to 4,294,967,295
float	4bytes	+/- 3.4e +/- 38 (~7 digits)
double	8bytes	+/- 1.7e +/- 308 (~15 digits)
long double	8bytes	+/- 1.7e +/- 308 (~15 digits)
wchar_t	2 or 4 bytes	1 wide character

The sizes of variables might be different from those shown in the above table, depending on the compiler and the computer you are using.

Following is the example, which will produce correct size of various data types on your computer.

```
#include<iostream>
using namespace std;

int main()
{
    cout << "Size of char : "<< sizeof(char) << endl;
    cout << "Size of int : "<< sizeof(int) << endl;
    cout << "Size of short int : "<< sizeof(shortint) <<
endl; cout << "Size of long int : "<< sizeof(longint) <<
endl; cout << "Size of float : "<< sizeof(float) << endl;
    cout << "Size of double : "<< sizeof(double) << endl;
    cout << "Size of wchar_t : "<< sizeof(wchar_t) << endl;
    return 0;
}
```

This example uses **endl**, which inserts a new-line character after every line and << operator is being used to pass multiple values out to the screen. We are also using **sizeof()** function to get size of various data types.

When the above code is compiled and executed, it produces the following result, which can vary from machine to machine:

```
Size of char:1
Size of int:4
Size of shortint:2
Size of longint:4
Size of float:4
Size of double:8
Size of wchar_t:4
```

typedef Declarations:

You can create a new name for an existing type using **typedef**. Following is the simple syntax to define a new type using typedef:

```
typedef type newname;
```

For example, the following tells the compiler that feet is another name for int:

```
typedef int feet;
```

Now, the following declaration is perfectly legal and creates an integer variable called distance:

```
feet distance;
```

Enumerated Types:

An enumerated type declares an optional type name and a set of zero or more identifiers that can be used as values of the type. Each enumerator is a constant whose type is the enumeration.

To create an enumeration requires the use of the keyword **enum**. The general form of an enumeration type is:

```
enumenum-name { list of names } var-list;
```

Here, the enum-name is the enumeration's type name. The list of names is comma separated.

For example, the following code defines an enumeration of colors called colors and the variable c of type color. Finally, c is assigned the value "blue".

```
enum color { red, green, blue } c;
c = blue;
```

By default, the value of the first name is 0, the second name has the value 1, the third has the value 2, and so on. But you can give a name a specific value by adding an initializer. For example, in the following enumeration, **green** will have the value 5.

```
enum color { red, green=5, blue };
```

Here, **blue** will have a value of 6 because each name will be one greater than the one that precedes it.

Variable Types

A variable provides us with named storage that our programs can manipulate. Each variable in C++ has a specific type, which determines the size and layout of the variable's memory; the range of values that can be stored within that memory; and the set of operations that can be applied to the variable.

The name of a variable can be composed of letters, digits, and the underscore character. It must begin with either a letter or an underscore. Upper and lowercase letters are distinct because C++ is case-sensitive:

There are following basic types of variable in C++ as explained in last chapter:

Type	Description
Bool	Stores either value true or false.
Char	Typically a single octet(one byte). This is an integer type.
Int	The most natural size of integer for the machine.
Float	A single-precision floating point value.
Double	A double-precision floating point value.
Void	Represents the absence of type.
wchar_t	A wide character type.

C++ also allows to define various other types of variables, which we will cover in subsequent chapters like **Enumeration**, **Pointer**, **Array**, **Reference**, **Data structures**, and **Classes**.

Following section will cover how to define, declare and use various types of variables.

Variable Definition in C++:

A variable definition means to tell the compiler where and how much to create the storage for the variable. A variable definition specifies a data type, and contains a list of one or more variables of that type as follows:

```
type variable_list;
```

Here, **type** must be a valid C++ data type including char, w_char, int, float, double, bool or any user-defined object, etc., and **variable_list** may consist of one or more identifier names separated by commas. Some valid declarations are shown here:

```
int    i, j, k;
char   c, ch;
float  f, salary;
double d;
```

The line **int i, j, k;** both declares and defines the variables i, j and k; which instructs the compiler to create variables named i, j and k of type int.

Variables can be initialized (assigned an initial value) in their declaration. The initializer consists of an equal sign followed by a constant expression as follows:

```
type variable_name = value;
```

Some examples are:

```
extern int d = 3, f = 5;    // declaration of d and f.
int d = 3, f = 5;          // definition and initializing d and f.
byte z  = 22;              // definition and initializes z.
char x  = 'x';             // the variable x has the value 'x'.
```

For definition without an initializer: variables with static storage duration are implicitly initialized with NULL (all bytes have the value 0); the initial value of all other variables is undefined.

Variable Declaration in C++:

A variable declaration provides assurance to the compiler that there is one variable existing with the given type and name so that compiler proceed for further compilation without needing complete detail about the variable. A variable declaration has its meaning at the time of compilation only, compiler needs actual variable declaration at the time of linking of the program.

A variable declaration is useful when you are using multiple files and you define your variable in one of the files, which will be available at the time of linking of the program. You will use extern keyword to declare a variable at any place. Though you can declare a variable multiple times in your C++ program, but it can be defined only once in a file, a function or a block of code.

Example

Try the following example where variables have been declared at the top, but they have been defined and initialized inside the main function:

```
#include<iostream>
using namespace std;

// Variable definition:
extern int a, b;
extern int c;
extern float f;

int main ()
{
    // Variable
    definition: int a, b;
```

```

int c;
float f;

// actual initialization
a =10;
b =20;
c = a + b;

cout << c << endl ;

f =70.0/3.0;
cout << f << endl ;

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

30
23.3333

```

Same concept applies on function declaration where you provide a function name at the time of its declaration and its actual definition can be given anywhere else. For example:

```

// function declaration
int func();

int main()
{
    // function call
    int i = func();
}

// function definition
int func()
{
    return 0;
}

```

Lvalues and Rvalues:

There are two kinds of expressions in C++:

- **lvalue:** An expression that is an lvalue may appear as either the left-hand or right-hand side of an assignment.
- **rvalue:** An expression that is an rvalue may appear on the right- but not left-hand side of an assignment.

Variables are lvalues and so may appear on the left hand side of an assignment. Numeric literals are rvalues and so may not be assigned and can not appear on the left-hand side. Following is a valid statement:

```

int g =20;

```

But following is not a valid statement and would generate compile-time error:

```

10=20;

```

Variable Scope

A scope is a region of the program and broadly speaking there are three places, where variables can be declared:

- Inside a function or a block which is called local variables,
- In the definition of function parameters which is called formal parameters.
- Outside of all functions which is called global variables.

We will learn what is a function and its parameter in subsequent chapters. Here, let us explain what are local and global variables.

Local Variables:

Variables that are declared inside a function or block are local variables. They can be used only by statements that are inside that function or block of code. Local variables are not known to functions outside their own. Following is the example using local variables:

```
#include<iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a, b;
    int c;

    // actual initialization
    a =10;
    b =20;
    c = a + b;

    cout << c;

    return 0;
}
```

Global Variables:

Global variables are defined outside of all the functions, usually on top of the program. The global variables will hold their value throughout the life-time of your program.

A global variable can be accessed by any function. That is, a global variable is available for use throughout your entire program after its declaration. Following is the example using global and local variables:

```
#include<iostream>
usingnamespace std;

// Global variable
declaration: int g;

int main ()
{
    // Local variable
    declaration: int a, b;

    // actual initialization
    a =10;
    b =20;
    g = a + b;

    cout << g;

    return0;
}
```

A program can have same name for local and global variables but value of local variable inside a function will take preference. For example:

```
#include<iostream>
usingnamespace std;

// Global variable
declaration: int g =20;

int main ()
{
    // Local variable
    declaration: int g =10;

    cout << g;

    return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
10
```

Initializing Local and Global Variables:

When a local variable is defined, it is not initialized by the system, you must initialize it yourself. Global variables are initialized automatically by the system when you define them as follows:

Data Type	Initializer
Int	0
Char	'\0'
Float	0
Double	0
Pointer	NULL

It is a good programming practice to initialize variables properly, otherwise sometimes program would produce unexpected result.

Constants/Literals

Constants refer to fixed values that the program may not alter and they are called **literals**.

Constants can be of any of the basic data types and can be divided into Integer Numerals, Floating-Point Numerals, Characters, Strings and Boolean Values.

Again, constants are treated just like regular variables except that their values cannot be modified after their definition.

Integer literals:

An integer literal can be a decimal, octal, or hexadecimal constant. A prefix specifies the base or radix: 0x or 0X for hexadecimal, 0 for octal, and nothing for decimal.

An integer literal can also have a suffix that is a combination of U and L, for unsigned and long, respectively. The suffix can be uppercase or lowercase and can be in any order.

Here are some examples of integer literals:

```
212// Legal
215u// Legal
0xFeeL// Legal
078// Illegal: 8 is not an octal digit
032UU// Illegal: cannot repeat a suffix
```

Following are other examples of various types of Integer literals:

```
85// decimal
0213// octal 0x4b//
hexadecimal 30//
int
30u// unsigned int
30l// long
30ul// unsigned long
```

Floating-point literals:

A floating-point literal has an integer part, a decimal point, a fractional part, and an exponent part. You can represent floating point literals either in decimal form or exponential form.

While representing using decimal form, you must include the decimal point, the exponent, or both and while representing using exponential form, you must include the integer part, the fractional part, or both. The signed exponent is introduced by e or E.

Here are some examples of floating-point literals:

```
3.14159 // Legal
314159E-5L // Legal
510E // Illegal: incomplete exponent
210f // Illegal: no decimal or exponent
.e55 // Illegal: missing integer or fraction
```

Boolean literals:

There are two Boolean literals and they are part of standard C++ keywords:

- A value of **true** representing true.
- A value of **false** representing false.

You should not consider the value of true equal to 1 and value of false equal to 0.

Character literals:

Character literals are enclosed in single quotes. If the literal begins with L (uppercase only), it is a wide character literal (e.g., L'x') and should be stored in **wchar_t** type of variable. Otherwise, it is a narrow character literal (e.g., 'x') and can be stored in a simple variable of **char** type.

A character literal can be a plain character (e.g., 'x'), an escape sequence (e.g., '\t'), or a universal character (e.g., '\u02C0').

There are certain characters in C++ when they are preceded by a backslash they will have special meaning and they are used to represent like new line (\n) or tab (\t). Here, you have a list of some of such escape sequence codes:

Escape sequence	Meaning
\\	\ character
'\'	' character
\"	" character
\?	? character
\a	Alert or bell
\b	Backspace
\f	Form feed
\n	Newline
\r	Carriage return
\t	Horizontal tab
\v	Vertical tab

\ooo	Octal number of one to three digits
\xhh...	Hexadecimal number of one or more digits

Following is the example to show few escape sequence characters:

```
#include<iostream>
usingnamespace std;

int main()
{
    cout <<"Hello\tWorld\n\n";
    return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
HelloWorld
```

String literals:

String literals are enclosed in double quotes. A string contains characters that are similar to character literals: plain characters, escape sequences, and universal characters.

You can break a long line into multiple lines using string literals and separate them using whitespaces.

Here are some examples of string literals. All the three forms are identical strings.

```
"hello, dear"

"hello, \
dear"

"hello, "d"ear"
```

Defining Constants:

There are two simple ways in C++ to define constants:

- Using **#define** preprocessor.
- Using **const** keyword.

The #define Preprocessor:

Following is the form to use #define preprocessor to define a constant:

```
#define identifier value
```

Following example explains it in detail:

```
#include<iostream>
usingnamespace std;

#define LENGTH 10
#define WIDTH 5
```

```

#define NEWLINE '\n'

int main()
{

    int area;

    area = LENGTH * WIDTH;
    cout << area;
    cout << NEWLINE;
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
50
```

The const Keyword:

You can use **const** prefix to declare constants with a specific type as follows:

```
const type variable = value;
```

Following example explains it in detail:

```

#include<iostream>
using namespace std;

int main()
{
    const int LENGTH = 10;
    const int WIDTH = 5;
    const char NEWLINE = '\n';
    int area;

    area = LENGTH * WIDTH;
    cout << area;
    cout << NEWLINE;
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
50
```

Note that it is a good programming practice to define constants in CAPITALS.

Modifier Types

C++ allows the **char**, **int**, and **double** data types to have modifiers preceding them. A modifier is used to alter the meaning of the base type so that it more precisely fits the needs of various situations.

The data type modifiers are listed here:

- **signed**
- **unsigned**
- **long**
- **short**

The modifiers **signed**, **unsigned**, **long**, and **short** can be applied to integer base types. In addition, **signed** and **unsigned** can be applied to **char**, and **long** can be applied to **double**.

The modifiers **signed** and **unsigned** can also be used as prefix to **long** or **short** modifiers. For example, **unsigned long int**.

C++ allows a shorthand notation for declaring **unsigned**, **short**, or **long** integers. You can simply use the word **unsigned**, **short**, or **long**, without the **int**. The **int** is implied. For example, the following two statements both declare unsigned integer variables.

```
unsigned x;  
unsignedint y;
```

To understand the difference between the way that signed and unsigned integer modifiers are interpreted by C++, you should run the following short program:

```
#include<iostream>  
usingnamespace std;  
  
/* This program shows the difference between  
 * signed and unsigned integers.  
 */  
int main()  
{  
    shortint i;// a signed short integer  
    shortunsignedint j;// an unsigned short integer  
  
    j =50000;
```

```
i = j;  
cout << i << " " << j;  
  
return 0;  
}
```

When this program is run, following is the output:

```
-1553650000
```

The above result is because the bit pattern that represents 50,000 as a short unsigned integer is interpreted as -15,536 by a short.

Type Qualifiers in C++

The type qualifiers provide additional information about the variables they precede.

Qualifier	Meaning
const	Objects of type const cannot be changed by your program during execution
volatile	The modifier volatile tells the compiler that a variable's value may be changed in ways not explicitly specified by the program.
restrict	A pointer qualified by restrict is initially the only means by which the object it points to can be accessed. Only C99 adds a new type qualifier called restrict.

Storage Classes

A storage class defines the scope (visibility) and life-time of variables and/or functions within a C++

Program. These specifiers precede the type that they modify. There are following storage classes, which can be used in a C++ Program

- auto
- register
- static
- extern
- mutable

The auto Storage Class

The **auto** storage class is the default storage class for all local variables.

```
{  
  int mount;  
  auto int month;  
}
```

The example above defines two variables with the same storage class, auto can only be used within functions, i.e., local variables.

The register Storage Class

The **register** storage class is used to define local variables that should be stored in a register instead of RAM. This means that the variable has a maximum size equal to the register size (usually one word) and can't have the unary '&' operator applied to it (as it does not have a memory location).

```
{  
  register int miles;  
}
```

The register should only be used for variables that require quick access such as counters. It should also be noted that defining 'register' does not mean that the variable will be stored in a register. It means that it MIGHT be stored in a register depending on hardware and implementation restrictions.

The static Storage Class

The **static** storage class instructs the compiler to keep a local variable in existence during the life-time of the program instead of creating and destroying it each time it comes into and goes out of scope. Therefore, making local variables static allows them to maintain their values between function calls.

The static modifier may also be applied to global variables. When this is done, it causes that variable's scope to be restricted to the file in which it is declared.

In C++, when static is used on a class data member, it causes only one copy of that member to be shared by all objects of its class.

```
#include<iostream>

// Function declaration
void func(void);

static int count = 10; /* Global variable */

main()
{
    while(count-->0)
    {
        func();
    }
    return 0;
}

// Function definition
void func(void)
{
    static int i = 5; // local static
    variable i++;
    std::cout << "i is " << i << " and count is " << count << std::endl;
}
```

When the above code is compiled and executed, it produces the following result:

```
i is 6 and count is 9
i is 7 and count is 8
i is 8 and count is 7
i is 9 and count is 6
i is 10 and count is 5
i is 11 and count is 4
i is 12 and count is 3
i is 13 and count is 2
i is 14 and count is 1
i is 15 and count is 0
```

The extern Storage Class

The **extern** storage class is used to give a reference of a global variable that is visible to ALL the program files. When you use 'extern' the variable cannot be initialized as all it does is point the variable name at a storage location that has been previously defined.

When you have multiple files and you define a global variable or function, which will be used in other files also, then *extern* will be used in another file to give reference of defined variable or function. Just for understanding, *extern* is used to declare a global variable or function in another file.

The *extern* modifier is most commonly used when there are two or more files sharing the same global variables or functions as explained below.

First File: main.cpp

```
#include<iostream>

int count ;
extern void write_extern();

main()
{
    count =5;
    write_extern();
}
```

Second File: write.cpp

```
#include<iostream>

extern int count;

void write_extern(void)
{
    std::cout << "Count is " << count << std::endl;
}
```

Here, *extern* keyword is being used to declare count in another file. Now, compile these two files as follows:

```
$g++ main.cpp write.cpp -o write
```

This will produce **write** executable program, try to execute **write** and check the result as follows:

```
$/write
5
```

The mutable Storage Class

The **mutable** specifier applies only to class objects, which are discussed later in this tutorial. It allows a member of an object to override constness. That is, a mutable member can be modified by a const member function.

Operators

An operator is a symbol that tells the compiler to perform specific mathematical or logical manipulations.

C++ is rich in built-in operators and provides the following types of operators:

- Arithmetic Operators
- Relational Operators
- Logical Operators
- Bitwise Operators
- Assignment Operators
- Misc Operators

This chapter will examine the arithmetic, relational, logical, bitwise, assignment and other operators one by one.

Arithmetic Operators:

There are following arithmetic operators supported by C++ language:

Assume variable A holds 10 and variable B holds 20, then:

Operator	Description	Example
+	Adds two operands	A + B will give 30
-	Subtracts second operand from the first	A - B will give -10
*	Multiplies both operands	A * B will give 200
/	Divides numerator by de-numerator	B / A will give 2
%	Modulus Operator and remainder of after an integer division	B % A will give 0
++	<u>Increment operator</u> , increases integer value by one	A++ will give 11

--	<u>Decrement operator</u> , decreases integer value by one	A-- will give 9
----	--	-----------------

Increment and Decrement operators

The increment operator ++ adds 1 to its operand, and the decrement operator -- subtracts 1 from its operand. Thus:

```
x = x+1;

is the same as

x++;
```

And similarly:

```
x = x-1;

is the same as

x--;
```

Both the increment and decrement operators can either precede (prefix) or follow (postfix) the operand. For example:

```
x = x+1;

can be written as

++x; // prefix form
```

or as:

```
x++; // postfix form
```

When an increment or decrement is used as part of an expression, there is an important difference in prefix and postfix forms. If you are using prefix form, then increment or decrement will be done before rest of the expression, and if you are using postfix form, then increment or decrement will be done after the complete expression is evaluated.

Example:

Following is the example to understand this difference:

```
#include<iostream>
using namespace std;

main()
{
    int a = 21;
    int c ;

    // Value of a will not be increased before assignment.
    c = a++;
    cout << "Line 1 - Value of a++ is : "<< c << endl ;

    // After expression value of a is increased
    cout << "Line 2 - Value of a is : "<< a << endl ;
```

```
// Value of a will be increased before assignment.
c =++a;
cout <<"Line 3 - Value of ++a is :"<< c << endl ;
return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Line1-Value of a++is:21
Line2-Value of a is:22
Line3-Value of ++a is:23
```

Example

Try the following example to understand all the arithmetic operators available in C++.

Copy and paste the following C++ program in test.cpp file and compile and run this program.

```
#include<iostream>
usingnamespace std;

main()
{
int a =21;
int b =10;
int c ;

c = a + b;
cout <<"Line 1 - Value of c is :"<< c << endl ;
c = a - b;
cout <<"Line 2 - Value of c is :"<< c << endl ;
c = a * b;
cout <<"Line 3 - Value of c is :"<< c << endl ;
c = a / b;
cout <<"Line 4 - Value of c is :"<< c << endl ;
c = a % b;
cout <<"Line 5 - Value of c is :"<< c << endl ;
c = a++;
cout <<"Line 6 - Value of c is :"<< c << endl ;
c = a--;
cout <<"Line 7 - Value of c is :"<< c << endl ;
return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Line1-Value of c is:31
Line2-Value of c is:11
Line3-Value of c is:210
Line4-Value of c is:2
Line5-Value of c is:1
Line6-Value of c is:21
Line7-Value of c is:22
```

Relational Operators:

There are following relational operators supported by C++ language

Assume variable A holds 10 and variable B holds 20, then:

Operator	Description	Example
==	Checks if the values of two operands are equal or not, if yes then condition becomes true.	(A == B) is not true.
!=	Checks if the values of two operands are equal or not, if values are not equal then condition becomes true.	(A != B) is true.
>	Checks if the value of left operand is greater than the value of right operand, if yes then condition becomes true.	(A > B) is not true.
<	Checks if the value of left operand is less than the value of right operand, if yes then condition becomes true.	(A < B) is true.
>=	Checks if the value of left operand is greater than or equal to the value of right operand, if yes then condition becomes true.	(A >= B) is not true.
<=	Checks if the value of left operand is less than or equal to the value of right operand, if yes then condition becomes true.	(A <= B) is true.

Example

Try the following example to understand all the relational operators available in C++.

Copy and paste the following C++ program in test.cpp file and compile and run this program.

```
#include<iostream>
usingnamespace std;

main()
{
    int a =21;
    int b =10;
    int c ;

    if( a == b )
    {
        cout <<"Line 1 - a is equal to b"<< endl ;
    }
    else
    {
        cout <<"Line 1 - a is not equal to b"<< endl ;
    }
    if( a < b )
    {
        cout <<"Line 2 - a is less than b"<< endl ;
    }
    else
    {
        cout <<"Line 2 - a is not less than b"<< endl ;
    }
    if( a > b )
```

```

{
    cout <<"Line 3 - a is greater than b"<< endl ;
}
else
{
    cout <<"Line 3 - a is not greater than b"<< endl ;
}
/* Let's change the values of a and b */
a =5;
b =20;
if( a <= b )
{
    cout <<"Line 4 - a is either less than \
                        or eugal to  b"<< endl ;
}
if( b >= a )
{
    cout <<"Line 5 - b is either greater than \
                        or equal to b"<< endl ;
}
return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Line1- a isnot equal to b
Line2- a isnot less than b
Line3- a is greater than b
Line4- a is either less than or eugal to  b
Line5- b is either greater than or equal to b

```

Logical Operators:

There are following logical operators supported by C++ language

Assume variable A holds 1 and variable B holds 0, then:

Operator	Description	Example
&&	Called Logical AND operator. If both the operands are non-zero, then condition becomes true.	(A && B) is false.
	Called Logical OR Operator. If any of the two operands is non-zero, then condition becomes true.	(A B) is true.
!	Called Logical NOT Operator. Use to reverses the logical state of its operand. If a condition is true, then Logical NOT operator will make false.	!(A && B) is true.

Example

Try the following example to understand all the logical operators available in C++.

Copy and paste the following C++ program in test.cpp file and compile and run this program.

```

#include<iostream>
using namespace std;

main()
{
    int a =5;
    int b =20;
    int c ;

    if( a && b )
    {
        cout <<"Line 1 - Condition is true"<< endl ;
    }
    if( a || b )
    {
        cout <<"Line 2 - Condition is true"<< endl ;
    }
    /* Let's change the values of a and b */
    a =0;
    b =10;
    if( a && b )
    {
        cout <<"Line 3 - Condition is true"<< endl ;
    }
    else
    {
        cout <<"Line 4 - Condition is not true"<< endl ;
    }
    if(!(a && b))
    {
        cout <<"Line 5 - Condition is true"<< endl ;
    }
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Line1-Condition is true
Line2-Condition is true
Line4-Condition is not true
Line5-Condition is true

```

Bitwise Operators:

Bitwise operator works on bits and performs bit-by-bit operation. The truth tables for &, |, and ^ are as follows:

p	q	p & q	p q	p ^ q
0	0	0	0	0
0	1	0	1	1
1	1	1	1	0
1	0	0	1	1

Assume if A = 60; and B = 13; now in binary format they will be as follows:

A = 0011 1100

B = 0000 1101

A&B = 0000 1100

A|B = 0011 1101

A^B = 0011 0001

~A = 1100 0011

The Bitwise operators supported by C++ language are listed in the following table. Assume variable A holds 60 and variable B holds 13, then:

Operator	Description	Example
&	Binary AND Operator copies a bit to the result if it exists in both operands.	(A & B) will give 12 which is 0000 1100
	Binary OR Operator copies a bit if it exists in either operand.	(A B) will give 61 which is 0011 1101
^	Binary XOR Operator copies the bit if it is set in one operand but not both.	(A ^ B) will give 49 which is 0011 0001
~	Binary Ones Complement Operator is unary and has the effect of 'flipping' bits.	(~A) will give -60 which is 1100 0011
<<	Binary Left Shift Operator. The left operands value is moved left by the number of bits specified by the right operand.	A << 2 will give 240 which is 1111 0000
>>	Binary Right Shift Operator. The left operands value is moved right by the number of bits specified by the right operand.	A >> 2 will give 15 which is 0000 1111

Example

Try the following example to understand all the bitwise operators available in C++.

Copy and paste the following C++ program in test.cpp file and compile and run this program.

```
#include<iostream>
using namespace std;

main()
{
    unsignedint a =60;           // 60 = 0011 1100
    unsignedint b =13;           // 13 = 0000 1101
    int c =0;

    c = a & b; // 12 = 0000 1100
    cout << "Line 1 - Value of c is : "<< c << endl ;

    c = a | b; // 61 = 0011 1101
    cout << "Line 2 - Value of c is: "<< c << endl ;

    c = a ^ b; // 49 = 0011 0001
```

```

cout <<"Line 3 - Value of c is: "<< c << endl ;

c =~a;// -61 = 1100 0011
cout <<"Line 4 - Value of c is: "<< c << endl ;

c = a <<2;// 240 = 1111 0000
cout <<"Line 5 - Value of c is: "<< c << endl ;

c = a >>2;// 15 = 0000 1111
cout <<"Line 6 - Value of c is: "<< c << endl ;

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Line1-Value of c is:12
Line2-Value of c is:61
Line3-Value of c is:49
Line4-Value of c is:-61
Line5-Value of c is:240
Line6-Value of c is:15

```

Assignment Operators:

There are following assignment operators supported by C++ language:

Operator	Description	Example
=	Simple assignment operator, Assigns values from right side operands to left side operand	C = A + B will assign value of A + B into C
+=	Add AND assignment operator, It adds right operand to the left operand and assign the result to left operand	C += A is equivalent to C = C + A
-=	Subtract AND assignment operator, It subtracts right operand from the left operand and assign the result to left operand	C -= A is equivalent to C = C - A
*=	Multiply AND assignment operator, It multiplies right operand with the left operand and assign the result to left operand	C *= A is equivalent to C = C * A
/=	Divide AND assignment operator, It divides left operand with the right operand and assign the result to left operand	C /= A is equivalent to C = C / A
%=	Modulus AND assignment operator, It takes modulus using two operands and assign the result to left operand	C %= A is equivalent to C = C % A
<<=	Left shift AND assignment operator	C <<= 2 is same as C = C << 2
>>=	Right shift AND assignment operator	C >>= 2 is same as C = C >> 2
&=	Bitwise AND assignment operator	C &= 2 is same as C = C & 2
^=	bitwise exclusive OR and assignment operator	C ^= 2 is same as C = C ^ 2

=	bitwise inclusive OR and assignment operator	C = 2 is same as C = C 2
---	--	-----------------------------

Example

Try the following example to understand all the assignment operators available in C++. Copy and paste the following C++ program in test.cpp file and compile and run this program.

```
#include<iostream>
using namespace std;

main()
{
    int a =21;
    int c ;

    c = a;
    cout <<"Line 1 - = Operator, Value of c = : "<<c<< endl ;

    c += a;
    cout <<"Line 2 - += Operator, Value of c = : "<<c<< endl ;

    c -= a;
    cout <<"Line 3 - -= Operator, Value of c = : "<<c<< endl ;

    c *= a;
    cout <<"Line 4 - *= Operator, Value of c = : "<<c<< endl ;

    c /= a;
    cout <<"Line 5 - /= Operator, Value of c = : "<<c<< endl ;

    c =200;
    c %= a;
    cout <<"Line 6 - %= Operator, Value of c = : "<<c<< endl ;

    c <=2;
    cout <<"Line 7 - <= Operator, Value of c = : "<<c<< endl ;

    c >=2;
    cout <<"Line 8 - >= Operator, Value of c = : "<<c<< endl ;

    c &=2;
    cout <<"Line 9 - &= Operator, Value of c = : "<<c<< endl ;

    c ^=2;
    cout <<"Line 10 - ^= Operator, Value of c = : "<<c<< endl ;

    c |=2;
    cout <<"Line 11 - |= Operator, Value of c = : "<<c<< endl ;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Line1-=Operator,Value of c =:21
Line2-+=Operator,Value of c =:42
Line3--=Operator,Value of c =:21
Line4-*=Operator,Value of c =:441
```

```

Line5- /=Operator, Value of c =: 21
Line6- %=Operator, Value of c =: 11
Line7- <=Operator, Value of c =: 44
Line8- >=Operator, Value of c =: 11
Line9- &=Operator, Value of c =: 2
Line10- ^=Operator, Value of c =: 0
Line11- |=Operator, Value of c =: 2

```

Misc Operators

There are few other operators supported by C++ Language.

Operator	Description
sizeof	sizeof operator returns the size of a variable. For example, sizeof(a), where a is integer, will return 4.
Condition ? X : Y	Conditional operator . If Condition is true ? then it returns value X : otherwise value Y
,	Comma operator causes a sequence of operations to be performed. The value of the entire comma expression is the value of the last expression of the comma-separated list.
. (dot) and -> (arrow)	Member operators are used to reference individual members of classes, structures, and unions.
Cast	Casting operators convert one data type to another. For example, int(2.2000) would return 2.
&	Pointer operator & returns the address of an variable. For example &a; will give actual address of the variable.
*	Pointer operator * is pointer to a variable. For example *var; will pointer to a variable var.

sizeof operator

The **sizeof** is a keyword, but it is a compile-time operator that determines the size, in bytes, of a variable or data type.

The sizeof operator can be used to get the size of classes, structures, unions and any other user defined data type.

The syntax of using sizeof is as follows:

```
sizeof(data type)
```

Where data type is the desired data type including classes, structures, unions and any other user defined data type.

Try the following example to understand all the sizeof operator available in C++. Copy and paste the following C++ program in test.cpp file and compile and run this program.

```

#include<iostream>
using namespace std;

int main()
{

```

```

cout <<"Size of char : "<<sizeof(char)<< endl;
cout <<"Size of int : "<<sizeof(int)<< endl;
cout <<"Size of short int : "<<sizeof(shortint)<<
endl; cout <<"Size of long int : "<<sizeof(longint)<<
endl; cout <<"Size of float : "<<sizeof(float)<< endl;
cout <<"Size of double : "<<sizeof(double)<< endl;
cout <<"Size of wchar_t : "<<sizeof(wchar_t)<< endl;
return 0;
}

```

When the above code is compiled and executed, it produces the following result, which can vary from machine to machine:

```

Size of char:1
Size of int:4
Size of shortint:2
Size of longint:4
Size of float:4
Size of double:8
Size of wchar_t:4

```

Conditional operator

```
Exp1?Exp2:Exp3;
```

where Exp1, Exp2, and Exp3 are expressions. Notice the use and placement of the colon. The value of a ? expression is determined like this: Exp1 is evaluated. If it is true, then Exp2 is evaluated and becomes the value of the entire ? expression. If Exp1 is false, then Exp3 is evaluated and its value becomes the value of the expression.

The ? is called a ternary operator because it requires three operands and can be used to replace if-else statements, which have the following form:

```

if(condition){
var= X; }else{
var= Y;
}

```

For example, consider the following code:

```

if(y <10){
var=30;
}else{
var=40;
}

```

Above code can be rewritten like this:

```
var=(y <10)?30:40;
```

Here, x is assigned the value of 30 if y is less than 10 and 40 if it is not.

Comma Operator

The purpose of comma operator is to string together several expressions. The value of a comma-separated list of expressions is the value of the right-most expression. Essentially, the comma's effect is to cause a sequence of operations to be performed.

The values of the other expressions will be discarded. This means that the expression on the right side will become the value of the entire comma-separated expression. For example:

```
var=(count=19, incr=10, count+1);
```

Here first assigns count the value 19, assigns incr the value 10, then adds 1 to count, and finally, assigns var the value of the rightmost expression, count+1, which is 20. The parentheses are necessary because the comma operator has a lower precedence than the assignment operator.

To see the effects of the comma operator, try running the following program:

```
#include<iostream>
using namespace std;

int main()
{
    int i, j;

    j =10;
    i =(j++, j+100,999+j);

    cout << i;

    return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
1010
```

Here is the procedure how the value of i gets calculated: j starts with the value 10. j is then incremented to 11. Next, j is added to 100. Finally, j (still containing 11) is added to 999, which yields the result 1010.

Member Operator

The . (dot) operator and the -> (arrow) operator are used to reference individual members of classes, structures, and unions.

The dot operator is applied to the actual object. The arrow operator is used with a pointer to an object. For example, consider the following structure:

```
struct Employee{ char
first_name[16]; int
age;
} emp;
```

The (.) dot operator:

To assign the value "zara" to the **first_name** member of object emp, you would write something as follows:

```
strcpy(emp.first_name, "zara");
```

The (->) arrow operator:

If p_emp is a pointer to an object of type Employee, then to assign the value "zara" to the **first_name** member of object emp, you would write something as follows:

```
strcpy(emp->first_name, "zara");
```

The -> is called the arrow operator. It is formed by using the minus sign followed by a greater than sign.

Simply saying: To access members of a structure, use the dot operator. To access members of a structure through a pointer, use the arrow operator.

Casting Operator

A cast is a special operator that forces one data type to be converted into another. As an operator, a cast is unary and has the same precedence as any other unary operator.

The most general cast supported by most of the C++ compilers is as follows:

```
(type) expression
```

Where type is the desired data type. There are other casting operators supported by C++, they are listed below:

- **const_cast<type> (expr):** The const_cast operator is used to explicitly override const and/or volatile in a cast. The target type must be the same as the source type except for the alteration of its const or volatile attributes. This type of casting manipulates the const attribute of the passed object, either to be set or removed.
- **dynamic_cast<type> (expr):** The dynamic_cast performs a runtime cast that verifies the validity of the cast. If the cast cannot be made, the cast fails and the expression evaluates to null. A dynamic_cast performs casts on polymorphic types and can cast a A* pointer into a B* pointer only if the object being pointed to actually is a B object.
- **reinterpret_cast<type> (expr):** The reinterpret_cast operator changes a pointer to any other type of pointer. It also allows casting from pointer to an integer type and vice versa.
- **static_cast<type> (expr):** The static_cast operator performs a nonpolymorphic cast. For example, it can be used to cast a base class pointer into a derived class pointer.

All of the above-mentioned casting operators will be used while working with classes and objects. For now, try the following example to understand a simple cast operator available in C++. Copy and paste the following C++ program in test.cpp file and compile and run this program.

```
#include<iostream>
using namespace std;

main()
{
    double a =21.09399;
    float b =10.20; int
    c ;

    c =(int) a;
    cout <<"Line 1 - Value of (int)a is : "<< c << endl ;

    c =(int) b;
    cout <<"Line 2 - Value of (int)b is  : "<< c << endl ;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Line1-Value of (int)a is:21
Line2-Value of (int)b is:10
```

Pointer Operator & and Pointer Operator *

C++ provides two pointer operators, which are (a) Address of Operator & and (b) Indirection Operator *.

A pointer is a variable that contains the address of another variable or you can say that a variable that contains the address of another variable is said to "point to" the other variable. A variable can be any data type including an object, structure or again pointer itself.

The . (dot) operator and the -> (arrow) operator are used to reference individual members of classes, structures, and unions.

The Address of Operator &:

The & is a unary operator that returns the memory address of its operand. For example, if var is an integer variable, then &var is its address. This operator has the same precedence and right-to-left associativity as the other unary operators.

You should read the & operator as "**the address of**" which means **&var** will be read as "the address of var".

The Indirection Operator *:

The second operator is indirection Operator *, and it is the complement of &. It is a unary operator that returns the value of the variable located at the address specified by its operand.

The following program executes the two operations

```
#include<iostream>

usingnamespace std;

int main ()
{
    intvar;
    int*ptr;
    int val;

    var=3000;

    // take the address of
    var ptr =&var;

    // take the value available at ptr
    val =*ptr;
    cout <<"Value of var :"<<var<< endl;
    cout <<"Value of ptr :"<< ptr << endl;
    cout <<"Value of val :"<< val << endl;

    return0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Value of var:3000
Value of ptr :0xbff64494
```

Value of val :3000

Operators Precedence in C++:

Operator precedence determines the grouping of terms in an expression. This affects how an expression is evaluated. Certain operators have higher precedence than others; for example, the multiplication operator has higher precedence than the addition operator:

For example, $x = 7 + 3 * 2$; here, x is assigned 13, not 20 because operator $*$ has higher precedence than $+$, so it first gets multiplied with $3*2$ and then adds into 7.

Here, operators with the highest precedence appear at the top of the table, those with the lowest appear at the bottom. Within an expression, higher precedence operators will be evaluated first.

Category	Operator	Associativity
Postfix	() [] -> . ++ --	Left to right
Unary	+ - ! ~ ++ -- (type)* & sizeof	Right to left
Multiplicative	* / %	Left to right
Additive	+ -	Left to right
Shift	<< >>	Left to right
Relational	<<= >>=	Left to right
Equality	== !=	Left to right
Bitwise AND	&	Left to right
Bitwise XOR	^	Left to right
Bitwise OR		Left to right
Logical AND	&&	Left to right
Logical OR		Left to right
Conditional	?:	Right to left
Assignment	= += -= *= /= %>>= <<= &= ^= =	Right to left
Comma	,	Left to right

Example

Try the following example to understand operators precedence concept available in C++. Copy and paste the following C++ program in test.cpp file and compile and run this program.

Check the simple difference with and without parenthesis. This will produce different results because $()$, $/$, $*$ and $+$ have different precedence. Higher precedence operators will be evaluated first:

```
#include<iostream>
using namespace std;

main()
{
```

```

int a =20;
int b =10;
int c =15;
int d =5;
int e;

e =(a + b)* c / d;// ( 30 * 15 ) / 5
cout <<"Value of (a + b) * c / d is :"<< e << endl ;

e =((a + b)* c)/ d;// (30 * 15 ) / 5
cout <<"Value of ((a + b) * c) / d is  :"<< e << endl ;

e =(a + b)*(c / d);// (30) * (15/5)
cout <<"Value of (a + b) * (c / d) is  :"<< e << endl ;

e = a +(b * c)/ d;// 20 + (150/5)
cout <<"Value of a + (b * c) / d is  :"<< e << endl ;

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Value of (a + b)* c / d is:90
Value of ((a + b)* c)/ d is:90
Value of (a + b)*(c / d)is:90
Value of a +(b * c)/ d is:50

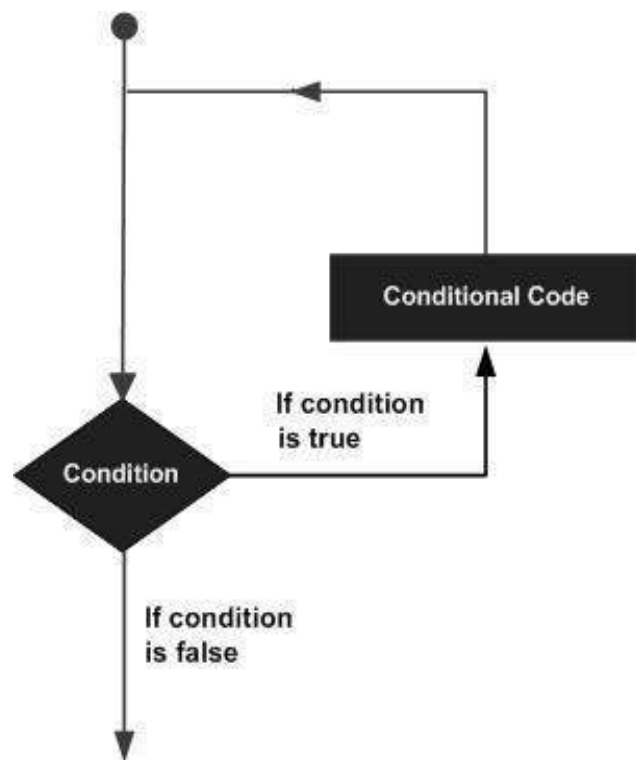

```

C++ Loop Types

There may be a situation, when you need to execute a block of code several number of times. In general, statements are executed sequentially: The first statement in a function is executed first, followed by the second, and so on.

Programming languages provide various control structures that allow for more complicated execution paths.

A loop statement allows us to execute a statement or group of statements multiple times and following is the general form of a loop statement in most of the programming languages:

C++ programming language provides the following types of loop to handle looping requirements. Click the following links to check their detail.

Loop Type	Description
while loop	Repeats a statement or group of statements while a given condition is true. It tests the condition before executing the loop body.
for loop	Execute a sequence of statements multiple times and abbreviates the code that manages the loop variable.
do...while loop	Like a while statement, except that it tests the condition at the end of the loop body
nested loops	You can use one or more loop inside any another while, for or do..while loop.

while loop

A **while** loop statement repeatedly executes a target statement as long as a given condition is true.

Syntax:

The syntax of a while loop in C++ is:

```
while(condition)
{
    statement(s);
}
```

Here, **statement(s)** may be a single statement or a block of statements. The **condition** may be any expression, and true is any nonzero value. The loop iterates while the condition is true.

When the condition becomes false, program control passes to the line immediately following the loop.

Flow Diagram:

Here, key point of the *while* loop is that the loop might not ever run. When the condition is tested and the result is false, the loop body will be skipped and the first statement after the while loop will be executed.

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a = 10;

    // while loop execution
    while( a < 20 )
    {
        cout << "value of a: " << a <<
        endl; a++;
    }

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
value of a: 10
value of a: 11
value of a: 12
```

```
value of a: 13  
value of a: 14  
value of a: 15  
value of a: 16  
value of a: 17  
value of a: 18  
value of a: 19
```

for loop

A **for** loop is a repetition control structure that allows you to efficiently write a loop that needs to execute a specific number of times.

Syntax:

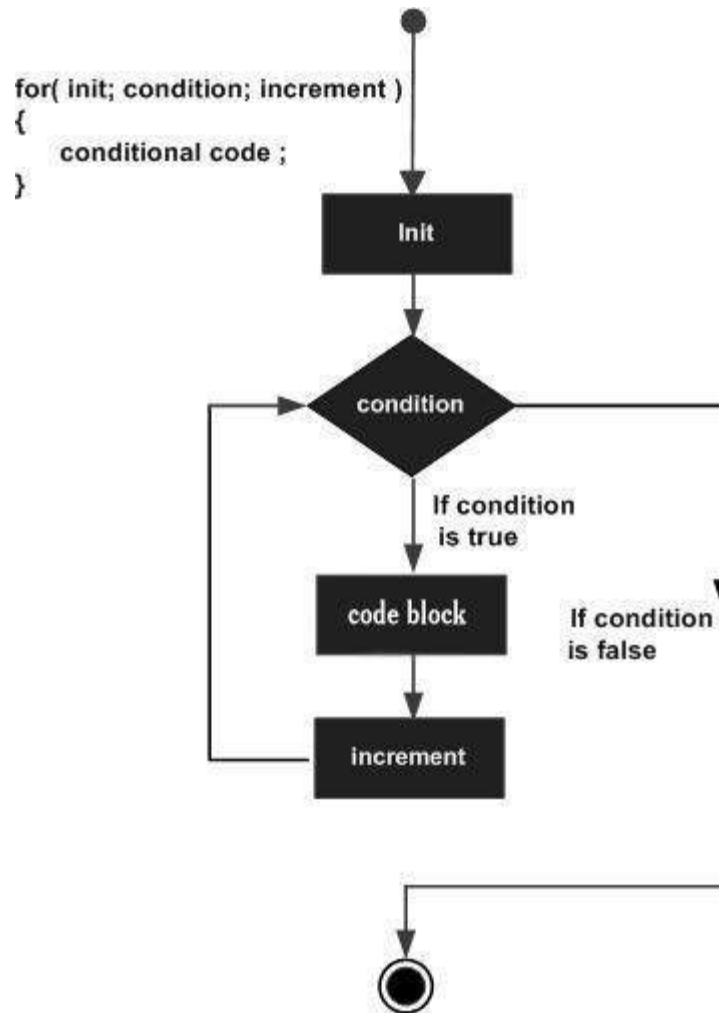

The syntax of a for loop in C++ is:

```
for ( init; condition; increment )  
{  
    statement(s);  
}
```

Here is the flow of control in a for loop:

- The **init** step is executed first, and only once. This step allows you to declare and initialize any loop control variables. You are not required to put a statement here, as long as a semicolon appears.
 - Next, the **condition** is evaluated. If it is true, the body of the loop is executed. If it is false, the body of the loop does not execute and flow of control jumps to the next statement just after the for loop.
 - After the body of the for loop executes, the flow of control jumps back up to the **increment** statement. This statement allows you to update any loop control variables. This statement can be left blank, as long as a semicolon appears after the condition.
 - The condition is now evaluated again. If it is true, the loop executes and the process repeats itself (body of loop, then increment step, and then again condition). After the condition becomes false, the for loop terminates.
-

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // for loop execution
    for( int a = 10; a < 20; a = a + 1 )
    {
        cout << "value of a: " << a << endl;
    }

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
value of a: 10
value of a: 11
```

```
value of a : 12
value of a : 13
value of a : 14
value of a : 15
value of a : 16
value of a : 17
value of a : 18
value of a : 19
```

do...while loop

Unlike **for** and **while** loops, which test the loop condition at the top of the loop, the **do...while** loop checks its condition at the bottom of the loop.

A **do...while** loop is similar to a while loop, except that a do...while loop is guaranteed to execute at least one time.

Syntax:

The syntax of a do...while loop in C++ is:

```
do
{
    statement(s);
}while( condition );
```

Notice that the conditional expression appears at the end of the loop, so the statement(s) in the loop execute once before the condition is tested.

If the condition is true, the flow of control jumps back up to do, and the statement(s) in the loop execute again. This process repeats until the given condition becomes false.

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a = 10;

    // do loop execution
    do
    {
        cout << "value of a: " << a <<
        endl; a = a + 1;
    }while( a < 20 );

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
value of a: 10
value of a: 11
value of a: 12
value of a: 13
value of a: 14
value of a: 15
value of a: 16
value of a: 17
value of a: 18
value of a: 19
```

nested loops

A loop can be nested inside of another loop. C++ allows at least 256 levels of nesting.

Syntax:

The syntax for a **nested for loop** statement in C++ is as follows:

```
for ( init; condition; increment )
{
    for ( init; condition; increment )
    {
        statement(s);
    }
    statement(s); // you can put more statetments.
}
```

The syntax for a **nested while loop** statement in C++ is as follows:

```
while(condition)
{
    while(condition)
    {
        statement(s);
    }
    statement(s); // you can put more statetments.
}
```

```
}
```

The syntax for a **nested do...while loop** statement in C++ is as follows:

```
do
{
    statement(s); // you can put more statetments.
    do
    {
        statement(s);
    }while( condition );
}while( condition );
```

Example:

The follow ing program uses a nested for loop to find the prime numbers from 2 to 100:

```
#include <iostream>
using namespace std;

int main ()
{
    int i, j;

    for(i=2; i<100; i++) {
        for(j=2; j <= (i/j); j++)
            if(!(i%j)) break; // if factor found, not prime
        if(j > (i/j)) cout << i << " is prime\n";
    }
    return 0;
}
```

This would produce the following result:

```
2 is prime
3 is prime
5 is prime
7 is prime
11 is prime
13 is prime
17 is prime
19 is prime
23 is prime
29 is prime
31 is prime
37 is prime
41 is prime
43 is prime
47 is prime
53 is prime
59 is prime
61 is prime
67 is prime
71 is prime
73 is prime
79 is prime
83 is prime
89 is prime
97 is prime
```

Loop Control Statements:

Loop control statements change execution from its normal sequence. When execution leaves a scope, all automatic objects that were created in that scope are destroyed.

C++ supports the following control statements. Click the following links to check their detail.

Control Statement	Description
break statement	Terminates the loop or switch statement and transfers execution to the statement immediately following the loop or switch.
continue statement	Causes the loop to skip the remainder of its body and immediately retest its condition prior to reiterating.
goto statement	Transfers control to the labeled statement. Though it is not advised to use goto statement in your program.

break statement

The **break** statement has the following two usages in C++:

- When the **break** statement is encountered inside a loop, the loop is immediately terminated and program control resumes at the next statement following the loop.
- It can be used to terminate a case in the **switch** statement (covered in the next chapter).

If you are using nested loops (i.e., one loop inside another loop), the break statement will stop the execution of the innermost loop and start executing the next line of code after the block.

Syntax:

The syntax of a break statement in C++ is:

```
break;
```

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a = 10;

    // do loop execution
    do
    {
        cout << "value of a: " << a << endl; a = a + 1;
        if( a > 15)
        {
            // terminate the loop break;
        }
    }while( a < 20 );

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
value of a: 10
value of a: 11
value of a: 12
value of a: 13
value of a: 14
value of a: 15
```

continue statement

The **continue** statement works somewhat like the break statement. Instead of forcing termination, however, continue forces the next iteration of the loop to take place, skipping any code in between.

For the **for** loop, continue causes the conditional test and increment portions of the loop to execute. For the **while** and **do...while** loops, program control passes to the conditional tests.

Syntax:

The syntax of a continue statement in C++ is:

```
continue;
```

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a = 10;

    // do loop execution
    do
    {
        if( a == 15)
        {
            // skip the iteration.
            a = a + 1;
        }
    }
}
```

```

        continue;
    }
    cout << "value of a: " << a <<
    endl; a = a + 1;
}while( a < 20 );

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

value of a: 10
value of a: 11
value of a: 12
value of a: 13
value of a: 14
value of a: 16
value of a: 17
value of a: 18
value of a: 19

```

goto statement

A **goto** statement provides an unconditional jump from the goto to a labeled statement in the same function.

NOTE: Use of **goto** statement is highly discouraged because it makes difficult to trace the control flow of a program, making the program hard to understand and hard to modify. Any program that uses a goto can be rewritten so that it doesn't need the goto.

Syntax:

The syntax of a goto statement in C++ is:

```

goto label;

..
.
label: statement;

```

Where **label** is an identifier that identifies a labeled statement. A labeled statement is any statement that is preceded by an identifier followed by a colon (:).

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // Local variable
    declaration: int a = 10;

    // do loop execution
    LOOP:do
    {
        if( a == 15)
        {
            // skip the iteration.
            a = a + 1;
            goto LOOP;
        }
        cout << "value of a: " << a <<
        endl; a = a + 1;
    }while( a < 20 );

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
value of a: 10
value of a: 11
value of a: 12
value of a: 13
value of a: 14
value of a: 16
value of a: 17
```

```
value of a: 18
value of a: 19
```

One good use for the `goto` is to exit from a deeply nested routine. For example, consider the following code fragment:

```
for(...) {
    for(...) {
        while(...) {
            if(...) goto stop;
            .
            .
            .
        }
    }
}
stop:
cout << "Error in program.\n";
```

Eliminating the **goto** would force a number of additional tests to be performed. A simple **break** statement would not work here, because it would only cause the program to exit from the innermost loop.

The Infinite Loop:

A loop becomes infinite loop if a condition never becomes false. The **for** loop is traditionally used for this purpose. Since none of the three expressions that form the for loop are required, you can make an endless loop by leaving the conditional expression empty.

```
#include<iostream>
using namespace std;

int main ()
{
    for(;;)
    {
        printf("This loop will run forever.\n");
    }

    return 0;
}
```

When the conditional expression is absent, it is assumed to be true. You may have an initialization and increment expression, but C++ programmers more commonly use the `for(;;)` construct to signify an infinite loop.

NOTE: You can terminate an infinite loop by pressing Ctrl + C keys.

Decision Making

Decision making structures require that the programmer specify one or more conditions to be evaluated or tested by the program, along with a statement or statements to be executed if the condition is determined to be true, and optionally, other statements to be executed if the condition is determined to be false.

Following is the general form of a typical decision making structure found in most of the programming languages:

C++ programming language provides following types of decision making statements. Click the following links to check their detail.

Statement	Description
if statement	An if statement consists of a boolean expression followed by one or more statements.

<u>if...else statement</u>	An if statement can be followed by an optional else statement, which executes when the boolean expression is false.
<u>switch statement</u>	A switch statement allows a variable to be tested for equality against a list of values.
<u>nested if statements</u>	You can use one if or else if statement inside another if or else if statement(s).
<u>nested switch statements</u>	You can use one switch statement inside another switch statement(s).

if statement

An **if** statement consists of a boolean expression followed by one or more statements.

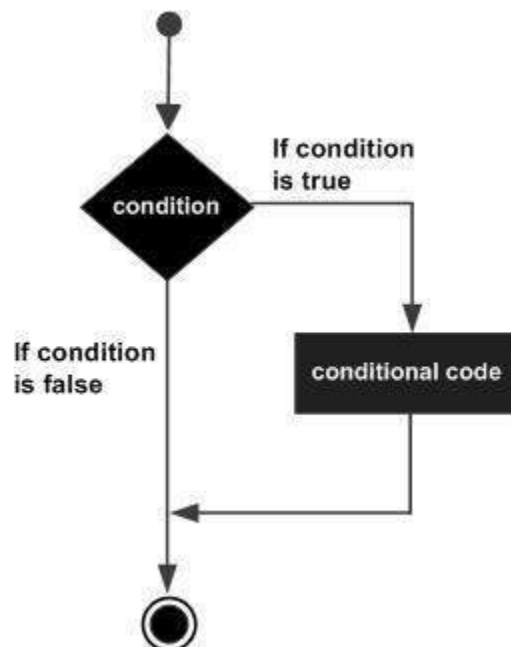

Syntax:

The syntax of an if statement in C++ is:

```
if(boolean_expression)
{
    // statement(s) will execute if the boolean expression is true
}
```

If the boolean expression evaluates to **true**, then the block of code inside the if statement will be executed. If boolean expression evaluates to **false**, then the first set of code after the end of the if statement (after the closing curly brace) will be executed.

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;
```

```

int main ()
{
    // local          variable
    declaration: int a = 10;

    // check    the    boolean
    condition if( a < 20 )
    {
        // if condition is true then print the
        // following cout << "a is less than 20;" << endl;
    }
    cout << "value of a is : " << a << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

a is less than 20;
value of a is : 10

```

if...else statement

An **if** statement can be followed by an optional **else** statement, which executes when the boolean expression is false.

Syntax:

The syntax of an if...else statement in C++ is:

```

if(boolean_expression)
{
    // statement(s) will execute if the boolean expression is true
}
else
{
    // statement(s) will execute if the boolean expression is false
}

```

If the boolean expression evaluates to **true**, then the **if block** of code will be executed, otherwise **else block** of code will be executed.

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // local variable
    declaration: int a = 100;

    // check the boolean
    condition if( a < 20 )
    {
        // if condition is true then print the
        following cout << "a is less than 20;" << endl;
    }
    else
    {
        // if condition is false then print the following
        cout << "a is not less than 20;" << endl;
    }
    cout << "value of a is : " << a << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
a is not less than 20;
value of a is : 100
```

The if...else if...else Statement:

An **if** statement can be followed by an optional **else if...else** statement, which is very useful to test various conditions using single if...else if statement.

When using if , else if , else statements there are few points to keep in mind.

- An if can have zero or one else's and it must come after any else if's.
- An if can have zero to many else if's and they must come before the else.
- Once an else if succeeds, none of the remaining else if's or else's will be tested.

Syntax:

The syntax of an if...else if...else statement in C++ is:

```
if(boolean_expression 1)
{
    // Executes when the boolean expression 1 is true
}
else if( boolean_expression 2)
{
    // Executes when the boolean expression 2 is true
}
else if( boolean_expression 3)
{
    // Executes when the boolean expression 3 is true
}
else
{
    // executes when the none of the above condition is true.
}
```

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // local variable
    declaration: int a = 100;

    // check the boolean
    condition if( a == 10 )
    {
        // if condition is true then print the
        following cout << "Value of a is 10" << endl;
    }
    else if( a == 20 )
    {
        // if else if condition is true cout
        << "Value of a is 20" << endl;
    }
    else if( a == 30 )
    {
```

```

        // if else if condition is true cout
        << "Value of a is 30" << endl;
    }
    else
    {
        // if none of the conditions is true
        cout << "Value of a is not matching" << endl;
    }
    cout << "Exact value of a is : " << a << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Value of a is not matching
Exact value of a is : 100

```

switch statement

A **switch** statement allows a variable to be tested for equality against a list of values. Each value is called a case, and the variable being switched on is checked for each case.

Syntax:

The syntax for a **switch** statement in C++ is as follows:

```

switch(expression){
    case constant-expression :
        statement(s);
        break; //optional
    case constant-expression :
        statement(s);
        break; //optional

    // you can have any number of case
    statements. default : //Optional
        statement(s);
}

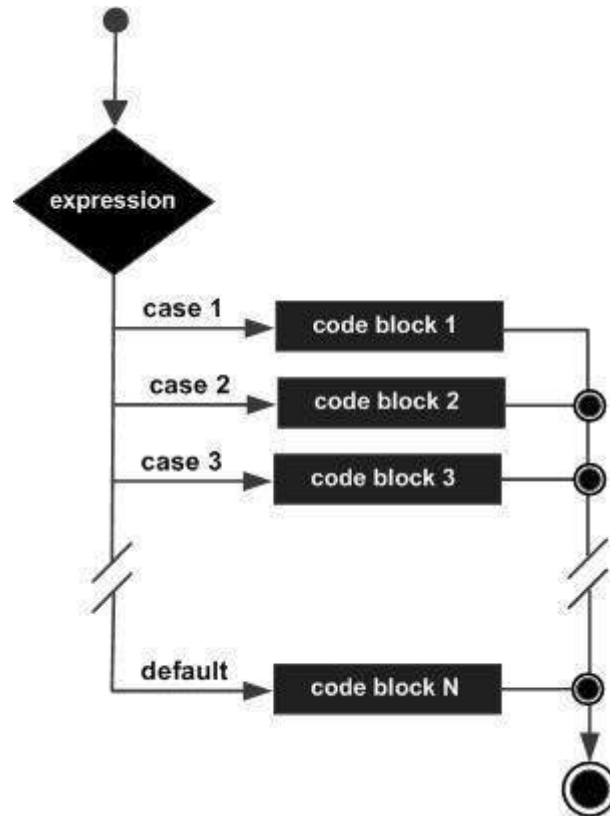

```

The following rules apply to a switch statement:

- The **expression** used in a **switch** statement must have an integral or enumerated type, or be of a class type in which the class has a single conversion function to an integral or enumerated type.
 - You can have any number of case statements within a switch. Each case is followed by the value to be compared to and a colon.
 - The **constant-expression** for a case must be the same data type as the variable in the switch, and it must be a constant or a literal.
 - When the variable being switched on is equal to a case, the statements following that case will execute until a **break** statement is reached.
 - When a break statement is reached, the switch terminates, and the flow of control jumps to the next line following the switch statement.
-

- Not every case needs to contain a break. If no break appears, the flow of control will *fall through* to subsequent cases until a break is reached.
- A **switch** statement can have an optional **default** case, which must appear at the end of the switch. The default case can be used for performing a task when none of the cases is true. No break is needed in the default case.

Flow Diagram:

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // local variable declaration:
    char grade = 'D';

    switch(grade)
    {
        case 'A' :
            cout << "Excellent!" << endl;
            break;
        case 'B' :
        case 'C' :
            cout << "Well done" << endl;
            break;
        case 'D' :
            cout << "You passed" << endl;
            break;
    }
```

```

case 'F' :
    cout << "Better try again" <<
    endl; break;
default :
    cout << "Invalid grade" << endl;
}
cout << "Your grade is " << grade << endl;

return 0;
}

```

This would produce the following result:

```

You passed
Your grade is D

```

nested if statements

It is always legal to **nest** if-else statements, which means you can use one if or else if statement inside another if or else if statement(s).

Syntax:

The syntax for a **nested if** statement is as follows:

```

if( boolean_expression 1)
{
    // Executes when the boolean expression 1 is true
    if(boolean_expression 2)
    {
        // Executes when the boolean expression 2 is true
    }
}

```

You can nest **else if...else** in the similar way as you have nested *if* statement.

Example:

```

#include <iostream>
using namespace std;

int main ()
{
    // local          variable
    declaration: int a = 100;
    int b = 200;

    // check          the          boolean
    condition if( a == 100 )
    {
        // if condition is true then check the
        following if( b == 200 )
        {
            // if condition is true then print the following
            cout << "Value of a is 100 and b is 200" << endl;
        }
    }

    cout << "Exact value of a is : " << a << endl;
    cout << "Exact value of b is : " << b << endl;
}

```

```
    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Value of a is 100 and b is 200
Exact value of a is : 100
Exact value of b is : 200
```

nested switch statements

It is possible to have a switch as part of the statement sequence of an outer switch. Even if the case constants of the inner and outer switch contain common values, no conflicts will arise.

C++ specifies that at least 256 levels of nesting be allowed for switch statements.

Syntax:

The syntax for a **nested switch** statement is as follows:

```
switch(ch1) {
    case 'A':
        cout << "This A is part of outer switch";
        switch(ch2) {
            case 'A':
                cout << "This A is part of inner
                switch"; break;
            case 'B': // ...
        }
        break;
    case 'B': // ...
}
```

Example:

```
#include <iostream>
using namespace std;

int main ()
{
    // local variable
    declaration: int a = 100;
    int b = 200;

    switch(a) {
        case 100:
            cout << "This is part of outer switch" <<
            endl; switch(b) {
                case 200:
                    cout << "This is part of inner switch" << endl;
            }
        }
    cout << "Exact value of a is : " << a << endl;
    cout << "Exact value of b is : " << b << endl;

    return 0;
}
```

```
}
```

This would produce the following result:

```
This is part of outer switch  
This is part of inner switch  
Exact value of a is : 100  
Exact value of b is : 200
```

The ? : Operator:

We have covered **conditional operator ? :** in previous chapter which can be used to replace **if...else** statements. It has the following general form:

```
Exp1 ? Exp2 : Exp3;
```

Where Exp1, Exp2, and Exp3 are expressions. Notice the use and placement of the colon.

The value of a ? expression is determined like this: Exp1 is evaluated. If it is true, then Exp2 is evaluated and becomes the value of the entire ? expression. If Exp1 is false, then Exp3 is evaluated and its value becomes the value of the expression.

Functions

A function is a group of statements that together perform a task. Every C++ program has at least one function, which is **main()**, and all the most trivial programs can define additional functions.

You can divide up your code into separate functions. How you divide up your code among different functions is up to you, but logically the division usually is so each function performs a specific task.

A function **declaration** tells the compiler about a function's name, return type, and parameters. A function **definition** provides the actual body of the function.

The C++ standard library provides numerous built-in functions that your program can call. For example, function **strcat()** to concatenate two strings, function **memcpy()** to copy one memory location to another location and many more functions.

A function is known as with various names like a method or a sub-routine or a procedure etc.

Defining a Function:

The general form of a C++ function definition is as follows:

```
return_type function_name( parameter list )
{
    body of the function
}
```

A C++ function definition consists of a function header and a function body. Here are all the parts of a function:

- **Return Type:** A function may return a value. The **return_type** is the data type of the value the function returns. Some functions perform the desired operations without returning a value. In this case, the **return_type** is the keyword **void**.
 - **Function Name:** This is the actual name of the function. The function name and the parameter list together constitute the function signature.
 - **Parameters:** A parameter is like a placeholder. When a function is invoked, you pass a value to the parameter. This value is referred to as actual parameter or argument. The parameter list refers to the type, order, and number of the parameters of a function. Parameters are optional; that is, a function may contain no parameters.
 - **Function Body:** The function body contains a collection of statements that define what the function does.
-

Example:

Following is the source code for a function called **max()**. This function takes two parameters num1 and num2 and returns the maximum between the two:

```
// function returning the max between two numbers

int max(int num1, int num2)
{
    // local variable declaration
    int result;

    if (num1 > num2)
        result = num1;
    else
        result = num2;

    return result;
}
```

Function Declarations:

A function **declaration** tells the compiler about a function name and how to call the function. The actual body of the function can be defined separately.

A function declaration has the following parts:

```
return_type function_name( parameter list );
```

For the above defined function max(), following is the function declaration:

```
int max(int num1, int num2);
```

Parameter names are not important in function declaration only their type is required, so following is also valid declaration:

```
int max(int, int);
```

Function declaration is required when you define a function in one source file and you call that function in another file. In such case, you should declare the function at the top of the file calling the function.

Calling a Function:

While creating a C++ function, you give a definition of what the function has to do. To use a function, you will have to call or invoke that function.

When a program calls a function, program control is transferred to the called function. A called function performs defined task and when its return statement is executed or when its function-ending closing brace is reached, it returns program control back to the main program.

To call a function, you simply need to pass the required parameters along with function name, and if function returns a value, then you can store returned value. For example:

```
#include <iostream>
using namespace std;
```

```

// function declaration
int max(int num1, int num2);

int main ()
{
    // local variable declaration: int a = 100;
    int b = 200;
    int ret;

    // calling a function to get max value.
    ret = max(a, b);

    cout << "Max value is : " << ret << endl;

    return 0;
}

// function returning the max between two numbers
int max(int num1, int num2)
{
    // local variable declaration
    int result;

    if (num1 > num2)
        result = num1;
    else
        result = num2;

    return result;
}

```

I kept max() function along with main() function and compiled the source code. While running final executable, it would produce the following result:

```
Max value is : 200
```

Function Arguments:

If a function is to use arguments, it must declare variables that accept the values of the arguments. These variables are called the **formal parameters** of the function.

The formal parameters behave like other local variables inside the function and are created upon entry into the function and destroyed upon exit.

While calling a function, there are two ways that arguments can be passed to a function:

Call Type	Description
<u>Call by value</u>	This method copies the actual value of an argument into the formal parameter of the function. In this case, changes made to the parameter inside the function have no effect on the argument.
<u>Call by pointer</u>	This method copies the address of an argument into the formal parameter. Inside the function, the address is used to access the actual argument used in the call. This means that changes made to the parameter affect the argument.

<u>Call by reference</u>	This method copies the reference of an argument into the formal parameter. Inside the function, the reference is used to access the actual argument used in the call. This means that changes made to the parameter affect the argument.
--------------------------	--

Call by value

The **call by value** method of passing arguments to a function copies the actual value of an argument into the formal parameter of the function. In this case, changes made to the parameter inside the function have no effect on the argument.

By default, C++ uses call by value to pass arguments. In general, this means that code within a function cannot alter the arguments used to call the function. Consider the function **swap()** definition as follows.

```
// function definition to swap the values.
void swap(int x, int y)
{
    int temp;

    temp = x; /* save the value of x
    */ x = y; /* put y into x */
    y = temp; /* put x into y */

    return;
}
```

Now, let us call the function **swap()** by passing actual values as in the following example:

```
#include <iostream>
using namespace std;

// function declaration
void swap(int x, int y);

int main ()
{
    // local variable
    // declaration: int a = 100;
    int b = 200;

    cout << "Before swap, value of a : " << a << endl;
    cout << "Before swap, value of b : " << b << endl;

    // calling a function to swap the values.
    swap(a, b);

    cout << "After swap, value of a : " << a << endl;
    cout << "After swap, value of b : " << b << endl;

    return 0;
}
```

When the above code is put together in a file, compiled and executed, it produces the following result:

```
Before swap, value of a :100
Before swap, value of b :200
After swap, value of a :100
After swap, value of b :200
```

Which shows that there is no change in the values though they had been changed inside the function.

Call by pointer

The **call by pointer** method of passing arguments to a function copies the address of an argument into the formal parameter. Inside the function, the address is used to access the actual argument used in the call. This means that changes made to the parameter affect the passed argument.

To pass the value by pointer, argument pointers are passed to the functions just like any other value. So accordingly you need to declare the function parameters as pointer types as in the following function **swap()**, which exchanges the values of the two integer variables pointed to by its arguments.

```
// function definition to swap the values.
void swap(int *x, int *y)
{
    int temp;
    temp = *x; /* save the value at address x */
    *x = *y; /* put y into x */
    *y = temp; /* put x into y */

    return;
}
```

To check the more detail about C++ pointers, kindly check [C++ Pointers](#) chapter.

For now, let us call the function **swap()** by passing values by pointer as in the following example:

```
#include <iostream>
using namespace std;

// function declaration
void swap(int *x, int *y);

int main ()
{
    // local variable
    declaration: int a = 100;
    int b = 200;

    cout << "Before swap, value of a :" << a << endl;
    cout << "Before swap, value of b :" << b << endl;

    /* calling a function to swap the values.
     * &a indicates pointer to a ie. address of variable a and
     * &b indicates pointer to b ie. address of variable b.
     */
    swap(&a, &b);

    cout << "After swap, value of a :" << a << endl;
    cout << "After swap, value of b :" << b << endl;

    return 0;
}
```

When the above code is put together in a file, compiled and executed, it produces the following result:

```
Before swap, value of a :100
Before swap, value of b :200
After swap, value of a :200
After swap, value of b :100
```

Call by reference

The **call by reference** method of passing arguments to a function copies the reference of an argument into the formal parameter. Inside the function, the reference is used to access the actual argument used in the call. This means that changes made to the parameter affect the passed argument.

To pass the value by reference, argument reference is passed to the functions just like any other value. So accordingly you need to declare the function parameters as reference types as in the following function **swap()**, which exchanges the values of the two integer variables pointed to by its arguments.

```
// function definition to swap the values.
void swap(int &x, int &y)
{
    int temp;
    temp = x; /* save the value at address x
    */ x = y; /* put y into x */
    y = temp; /* put x into y */

    return;
}
```

For now, let us call the function **swap()** by passing values by reference as in the following example:

```
#include <iostream>
using namespace std;

// function declaration
void swap(int &x, int &y);

int main ()
{
    // local variable
    declaration: int a = 100;
    int b = 200;

    cout << "Before swap, value of a :" << a << endl;
    cout << "Before swap, value of b :" << b << endl;

    /* calling a function to swap the values using variable
    reference.*/ swap(a, b);

    cout << "After swap, value of a :" << a << endl;
    cout << "After swap, value of b :" << b << endl;

    return 0;
}
```

When the above code is put together in a file, compiled and executed, it produces the following result:

```
Before swap, value of a :100
Before swap, value of b :200
After swap, value of a :200
After swap, value of b :100
```

By default, C++ uses **call by value** to pass arguments. In general, this means that code within a function cannot alter the arguments used to call the function and above mentioned example while calling **max()** function used the same method.

Default Values for Parameters:

When you define a function, you can specify a default value for each of the last parameters. This value will be used if the corresponding argument is left blank when calling to the function.

This is done by using the assignment operator and assigning values for the arguments in the function definition. If a value for that parameter is not passed when the function is called, the default given value is used, but if a value is specified this default value is ignored and the passed value is used instead. Consider the following example:

```
#include <iostream>
using namespace std;

int sum(int a, int b=20)
{
    int result;

    result = a + b;

    return (result);
}

int main ()
{
    // local
    declaration: int a = 100;
    int b = 200;
    int result;

    // calling a function to add the
    values. result = sum(a, b);
    cout << "Total value is :" << result << endl;

    // calling a function again as follows.
    result = sum(a);
    cout << "Total value is :" << result << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Total value is :300
Total value is :120
```

Numbers

Normally, when we work with Numbers, we use primitive data types such as int, short, long, float and double, etc. The number data types, their possible values and number ranges have been explained while discussing C++ Data Types.

Defining Numbers in C++:

You have already defined numbers in various examples given in previous chapters. Here is another consolidated example to define various types of numbers in C++:

```
#include <iostream>
using namespace std;

int main ()
{
    // number definition:
    short s;
    int i;
    long l;
    float f;
    double d;

    // number assignments;
    s = 10;
    i = 1000;
    l = 1000000;
    f = 230.47;
    d = 30949.374;

    // number printing;
    cout << "short s :" << s << endl;
    cout << "int i :" << i << endl;
    cout << "long l :" << l << endl;
    cout << "float f :" << f << endl;
    cout << "double d :" << d << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
short s :10
int i :1000
long l :1000000
float f :230.47
double d :30949.4
```

Math Operations in C++:

In addition to the various functions you can create, C++ also includes some useful functions you can use. These functions are available in standard C and C++ libraries and called **built-in** functions. These are functions that can be included in your program and then use.

C++ has a rich set of mathematical operations, which can be performed on various numbers. Following table lists down some useful built-in mathematical functions available in C++.

To utilize these functions you need to include the math header file **<cmath>**.

S.N.	Function & Purpose
1	double cos(double); This function takes an angle (as a double) and returns the cosine.
2	double sin(double); This function takes an angle (as a double) and returns the sine.
3	double tan(double); This function takes an angle (as a double) and returns the tangent.
4	double log(double); This function takes a number and returns the natural log of that number.
5	double pow(double, double); The first is a number you wish to raise and the second is the power you wish to raise it to.
6	double hypot(double, double); If you pass this function the length of two sides of a right triangle, it will return you the length of the hypotenuse.
7	double sqrt(double); You pass this function a number and it gives you this square root.
8	int abs(int); This function returns the absolute value of an integer that is passed to it.
9	double fabs(double); This function returns the absolute value of any decimal number passed to it.
10	double floor(double); Finds the integer which is less than or equal to the argument passed to it.

Following a simple example to show few of the mathematical operations:

```
#include <iostream>
#include <cmath>
using namespace std;

int main ()
{
    // number definition:
```

```

short   s = 10;
int     i = -1000;
long    l = 100000;
float   f = 230.47;
double  d = 200.374;

// mathematical operations;
cout << "sin(d) :" << sin(d) << endl;
cout << "abs(i) :" << abs(i) << endl;
cout << "floor(d) :" << floor(d) << endl;
cout << "sqrt(f) :" << sqrt(f) << endl;
cout << "pow( d, 2) :" << pow(d, 2) << endl;

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

sign(d) :-0.634939
abs(i) :1000 floor(d)
:200 sqrt(f) :15.1812
pow( d, 2 ) :40149.7

```

Random Numbers in C++:

There are many cases where you will wish to generate a random number. There are actually two functions you will need to know about random number generation. The first is **rand()**, this function will only return a pseudo random number. The way to fix this is to first call the **srand()** function.

Following is a simple example to generate few random numbers. This example makes use of **time()** function to get the number of seconds on your system time, to randomly seed the rand() function:

```

#include <iostream>
#include <ctime>
#include <cstdlib>

using namespace std;

int main ()
{
    int i,j;

    // set the seed
    srand( (unsigned)time( NULL ) );

    /* generate 10 random numbers. */
    for( i = 0; i < 10; i++ )
    {
        // generate actual random number
        j= rand();
        cout << " Random Number : " << j << endl;
    }

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
Random Number : 1748144778
Random Number : 630873888
Random Number : 2134540646
Random Number : 219404170
Random Number : 902129458
Random Number : 920445370
Random Number : 1319072661
Random Number : 257938873
Random Number : 1256201101
Random Number : 580322989
```

Arrays

C++ provides a data structure, **the array**, which stores a fixed-size sequential collection of elements of the

same type. An array is used to store a collection of data, but it is often more useful to think of an array as a collection of variables of the same type.

Instead of declaring individual variables, such as `number0`, `number1`, ..., and `number99`, you declare one array variable such as `numbers` and use `numbers[0]`, `numbers[1]`, and ..., `numbers[99]` to represent individual variables. A specific element in an array is accessed by an index.

All arrays consist of contiguous memory locations. The lowest address corresponds to the first element and the highest address to the last element.

Declaring Arrays:

To declare an array in C++, the programmer specifies the type of the elements and the number of elements required by an array as follows:

```
type arrayName [ arraySize ];
```

This is called a single-dimension array. The **arraySize** must be an integer constant greater than zero and **type** can be any valid C++ data type. For example, to declare a 10-element array called `balance` of type `double`, use this statement:

```
double balance[10];
```

Initializing Arrays:

You can initialize C++ array elements either one by one or using a single statement as follows:

```
double balance[5] = {1000.0, 2.0, 3.4, 17.0, 50.0};
```

The number of values between braces `{ }` can not be larger than the number of elements that we declare for the array between square brackets `[]`. Following is an example to assign a single element of the array:

If you omit the size of the array, an array just big enough to hold the initialization is created. Therefore, if you write:

```
double balance[] = {1000.0, 2.0, 3.4, 17.0, 50.0};
```

You will create exactly the same array as you did in the previous example.

```
balance[4] = 50.0;
```

The above statement assigns element number 5th in the array a value of 50.0. Array with 4th index will be 5th, i.e., last element because all arrays have 0 as the index of their first element which is also called base index. Following is the pictorial representation of the same array we discussed above:

	0	1	2	3	4
balance	1000.0	2.0	3.4	7.0	50.0

Accessing Array Elements:

An element is accessed by indexing the array name. This is done by placing the index of the element within square brackets after the name of the array. For example:

```
double salary = balance[9];
```

The above statement will take 10th element from the array and assign the value to salary variable. Following is an example, which will use all the above-mentioned three concepts viz. declaration, assignment and accessing arrays:

```
#include <iostream>
using namespace std;

#include <iomanip>
using std::setw;

int main ()
{
    int n[ 10 ]; // n is an array of 10 integers

    // initialize elements of array n to
    0 for ( int i = 0; i < 10; i++ )
    {
        n[ i ] = i + 100; // set element at location i to i + 100
    }
    cout << "Element" << setw( 13 ) << "Value" << endl;

    // output each array element's value
    for ( int j = 0; j < 10; j++ )
    {
        cout << setw( 7 ) << j << setw( 13 ) << n[ j ] << endl;
    }

    return 0;
}
```

This program makes use of **setw()** function to format the output. When the above code is compiled and executed, it produces the following result:

Element	Value
0	100
1	101
2	102
3	103
4	104
5	105

```
6      106
7      107
8      108
9      109
```

C++ Arrays in Detail:

Arrays are important to C++ and should need lots of more detail. There are following few important concepts, which should be clear to a C++ programmer:

Concept	Description
Multi-dimensional arrays	C++ supports multidimensional arrays. The simplest form of the multidimensional array is the two-dimensional array.
Pointer to an array	You can generate a pointer to the first element of an array by simply specifying the array name, without any index.
Passing arrays to functions	You can pass to the function a pointer to an array by specifying the array's name without an index.
Return array from functions	C++ allows a function to return an array.

Multi-dimensional arrays

C++ allows multidimensional arrays. Here is the general form of a multidimensional array declaration:

```
type name[size1][size2]...[sizeN];
```

For example, the following declaration creates a three dimensional 5 . 10 . 4 integer array:

```
int threedim[5][10][4];
```

Two-Dimensional Arrays:

The simplest form of the multidimensional array is the two-dimensional array. A two-dimensional array is, in essence, a list of one-dimensional arrays. To declare a two-dimensional integer array of size x,y, you would write something as follows:

```
type arrayName [ x ][ y ];
```

Where **type** can be any valid C++ data type and **arrayName** will be a valid C++ identifier.

A two-dimensional array can be think as a table, which will have x number of rows and y number of columns. A 2-dimensional array **a**, which contains three rows and four columns can be shown as below:

	Column 0	Column 1	Column 2	Column 3
Row 0	a[0][0]	a[0][1]	a[0][2]	a[0][3]
Row 1	a[1][0]	a[1][1]	a[1][2]	a[1][3]
Row 2	a[2][0]	a[2][1]	a[2][2]	a[2][3]

Thus, every element in array **a** is identified by an element name of the form **a[i][j]**, where **a** is the name of the array, and **i** and **j** are the subscripts that uniquely identify each element in **a**.

Initializing Two-Dimensional Arrays:

Multidimensioned arrays may be initialized by specifying bracketed values for each row. Following is an array with 3 rows and each row have 4 columns.

```
int a[3][4] = {
    {0, 1, 2, 3}, /* initializers for row indexed by 0 */
    {4, 5, 6, 7}, /* initializers for row indexed by 1 */
    {8, 9, 10, 11} /* initializers for row indexed by 2 */
};
```

The nested braces, which indicate the intended row, are optional. The following initialization is equivalent to previous example:

```
int a[3][4] = {0,1,2,3,4,5,6,7,8,9,10,11};
```

Accessing Two-Dimensional Array Elements:

An element in 2-dimensional array is accessed by using the subscripts ie. row index and column index of the array. For example:

```
int val = a[2][3];
```

The above statement will take 4th element from the 3rd row of the array. You can verify it in the above digram.

```
#include <iostream>
using namespace std;

int main ()
{
    // an array with 5 rows and 2 columns.
    int a[5][2] = { {0,0}, {1,2}, {2,4}, {3,6},{4,8}};

    // output each array element's value
    for ( int i = 0; i < 5; i++ )
        for ( int j = 0; j < 2; j++ )
        {
            cout << "a[" << i << "][" << j << "]:
            "; cout << a[i][j]<< endl;
        }

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
a[0][0]: 0
a[0][1]: 0
a[1][0]: 1
a[1][1]: 2
a[2][0]: 2
a[2][1]: 4
a[3][0]: 3
a[3][1]: 6
a[4][0]: 4
a[4][1]: 8
```

As explained above, you can have arrays with any number of dimensions, although it is likely that most of the arrays you create will be of one or two dimensions.

Pointer to an array

It is most likely that you would not understand this chapter until you go through the chapter related C++ Pointers.

So assuming you have bit understanding on pointers in C++, let us start: An array name is a constant pointer to the first element of the array. Therefore, in the declaration:

```
double balance[50];
```

balance is a pointer to &balance[0], which is the address of the first element of the array balance. Thus, the following program fragment assigns **p** the address of the first element of **balance**:

```
double *p;
double balance[10];

p = balance;
```

It is legal to use array names as constant pointers, and vice versa. Therefore, *(balance + 4) is a legitimate way of accessing the data at balance[4].

Once you store the address of first element in p, you can access array elements using *p, *(p+1), *(p+2) and so on. Below is the example to show all the concepts discussed above:

```
#include <iostream>
using namespace std;

int main ()
{
    // an array with 5 elements.
    double balance[5] = {1000.0, 2.0, 3.4, 17.0, 50.0};
    double *p;

    p = balance;

    // output each array element's value
    cout << "Array values using pointer " << endl;
    for ( int i = 0; i < 5; i++ )
    {
        cout << "*(p + " << i << " ) : ";
        cout << *(p + i) << endl;
    }

    cout << "Array values using balance as address " << endl;
    for ( int i = 0; i < 5; i++ )
    {
        cout << "*(balance + " << i << " ) : ";
        cout << *(balance + i) << endl;
    }

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Array values using
pointer *(p + 0) : 1000
```

```

*(p + 1) : 2
*(p + 2) : 3.4
*(p + 3) : 17
*(p + 4) : 50
Array values using balance as address
*(balance + 0) : 1000
*(balance + 1) : 2
*(balance + 2) : 3.4
*(balance + 3) : 17
*(balance + 4) : 50

```

In the above example, p is a pointer to double which means it can store address of a variable of double type. Once we have address in p, then *p will give us value available at the address stored in p, as we have shown in the above example.

Passing arrays to functions

C++ does not allow to pass an entire array as an argument to a function. However, You can pass a pointer to an array by specifying the array's name without an index.

If you want to pass a single-dimension array as an argument in a function, you would have to declare function formal parameter in one of following three ways and all three declaration methods produce similar results because each tells the compiler that an integer pointer is going to be received.

Way-1

Formal parameters as a pointer as follows:

```

void myFunction(int *param)
{
.
.
.
}

```

Way-2

Formal parameters as a sized array as follows:

```

void myFunction(int param[10])
{
.
.
.
}

```

Way-3

Formal parameters as an unsized array as follows:

```

void myFunction(int param[])
{
.
.
.
}

```

Now, consider the following function, which will take an array as an argument along with another argument and based on the passed arguments, it will return average of the numbers passed through the array as follows:

```
double getAverage(int arr[], int size)
{
    int i, sum = 0;
    double avg;

    for (i = 0; i < size; ++i)
    {
        sum += arr[i];
    }

    avg = double(sum) / size;

    return avg;
}
```

Now, let us call the above function as follows:

```
#include <iostream>
using namespace std;

// function declaration:
double getAverage(int arr[], int size);

int main ()
{
    // an int array with 5 elements.
    int balance[5] = {1000, 2, 3, 17,
    50}; double avg;

    // pass pointer to the array as an argument.
    avg = getAverage( balance, 5 );

    // output the returned value
    cout << "Average value is: " << avg << endl;

    return 0;
}
```

When the above code is compiled together and executed, it produces the following result:

```
Average value is: 214.4
```

As you can see, the length of the array doesn't matter as far as the function is concerned because C++ performs no bounds checking for the formal parameters.

Return array from functions

C++ does not allow to return an entire array as an argument to a function. However, You can return a pointer to an array by specifying the array's name without an index.

If you want to return a single-dimension array from a function, you would have to declare a function returning a pointer as in the following example:

```
int * myFunction( )
{
    .
    .
    .
}
```

```
.  
}
```

Second point to remember is that C++ does not advocate to return the address of a local variable to outside of the function so you would have to define the local variable as **static** variable.

Now, consider the following function, which will generate 10 random numbers and return them using an array and call this function as follows:

```
#include <iostream>
#include <ctime>

using namespace std;

// function to generate and retrun random
numbers. int * getRandom( )
{
    static int r[10];

    // set the seed
    srand( (unsigned)time( NULL ) );
    for (int i = 0; i < 10; ++i)
    {
        r[i] = rand();
        cout << r[i] << endl;
    }

    return r;
}

// main function to call above defined
function. int main ( )
{
    // a pointer to an
    int. int *p;

    p = getRandom();
    for ( int i = 0; i < 10; i++ )
    {
        cout << *(p + " << i << " ) : ";
        cout << *(p + i) << endl;
    }

    return 0;
}
```

When the above code is compiled together and executed, it produces result something as follows:

```
624723190
1468735695
807113585
976495677
613357504
1377296355
1530315259
1778906708
1820354158
667126415

*(p + 0) : 624723190
*(p + 1) : 1468735695
*(p + 2) : 807113585
```

```
*(p + 3) : 976495677
*(p + 4) : 613357504
*(p + 5) : 1377296355
*(p + 6) : 1530315259
*(p + 7) : 1778906708
*(p + 8) : 1820354158
*(p + 9) : 667126415
```

Strings

C++ provides following two types of string representations:

- The C-style character string.
- The string class type introduced with Standard C++.

The C-Style Character String:

The C-style character string originated within the C language and continues to be supported within C++. This string is actually a one-dimensional array of characters which is terminated by a **null** character '\0'. Thus a null-terminated string contains the characters that comprise the string followed by a **null**.

The following declaration and initialization create a string consisting of the word "Hello". To hold the null character at the end of the array, the size of the character array containing the string is one more than the number of characters in the word "Hello."

```
char greeting[6] = {'H', 'e', 'l', 'l', 'o', '\0'};
```

If you follow the rule of array initialization, then you can write the above statement as follows:

```
char greeting[] = "Hello";
```

Following is the memory presentation of above defined string in C/C++:

Actually, you do not place the null character at the end of a string constant. The C++ compiler automatically places the '\0' at the end of the string when it initializes the array. Let us try to print above-mentioned string:

```
#include <iostream>
using namespace std;
int main ()
{
    char greeting[6] = {'H', 'e', 'l', 'l', 'o', '\0'};
    cout << "Greeting message: ";
```

```

    cout << greeting << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces result something as follows:

```
Greeting message: Hello
```

C++ supports a wide range of functions that manipulate null-terminated strings:

S.N.	Function & Purpose
1	strcpy(s1, s2); Copies string s2 into string s1.
2	strcat(s1, s2); Concatenates string s2 onto the end of string s1.
3	strlen(s1); Returns the length of string s1.
4	strcmp(s1, s2); Returns 0 if s1 and s2 are the same; less than 0 if s1<s2; greater than 0 if s1>s2.
5	strchr(s1, ch); Returns a pointer to the first occurrence of character ch in string s1.
6	strstr(s1, s2); Returns a pointer to the first occurrence of string s2 in string s1.

Following example makes use of few of the above-mentioned functions:

```

#include <iostream>
#include <cstring>

using namespace std;

int main ()
{
    char str1[10] = "Hello";
    char str2[10] = "World";
    char str3[10];
    int len ;

    // copy str1 into str3
    strcpy( str3, str1);
    cout << "strcpy( str3, str1) : " << str3 << endl;

    // concatenates str1 and str2
    strcat( str1, str2);
    cout << "strcat( str1, str2): " << str1 << endl;

    // total length of str1 after concatenation
    len = strlen(str1);
    cout << "strlen(str1) : " << len << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces result something as follows:

```
strcpy( str3, str1) : Hello
strcat( str1, str2):
HelloWorld strlen(str1) : 10
```

The String Class in C++:

The standard C++ library provides a **string** class type that supports all the operations mentioned above, additionally much more functionality. We will study this class in C++ Standard Library but for now let us check following example:

At this point, you may not understand this example because so far we have not discussed Classes and Objects. So can have a look and proceed until you have understanding on Object Oriented Concepts.

```
#include <iostream>
#include <string>

using namespace std;

int main ()
{
    string str1 = "Hello";
    string str2 = "World";
    string str3;
    int len ;

    // copy str1 into str3
    str3 = str1;
    cout << "str3 : " << str3 << endl;

    // concatenates str1 and str2
    str3 = str1 + str2;
    cout << "str1 + str2 : " << str3 << endl;

    // total length of str3 after concatenation
    len = str3.size();
    cout << "str3.size() : " << len << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces result something as follows:

```
str3 : Hello
str1 + str2 : HelloWorld
str3.size() : 10
```

Pointers

C++ pointers are easy and fun to learn. Some C++ tasks are performed more easily with pointers, and other C++ tasks, such as dynamic memory allocation, cannot be performed without them.

As you know every variable is a memory location and every memory location has its address defined which can be accessed using ampersand (&) operator which denotes an address in memory. Consider the following which will print the address of the variables defined:

```
#include <iostream>

using namespace std;

int main ()
{
    int var1; char
    var2[10];

    cout << "Address of var1 variable: ";
    cout << &var1 << endl;

    cout << "Address of var2 variable: ";
    cout << &var2 << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces result something as follows:

```
Address of var1 variable: 0xbfebd5c0
Address of var2 variable: 0xbfebd5b6
```

What Are Pointers?

A **pointer** is a variable whose value is the address of another variable. Like any variable or constant, you must declare a pointer before you can work with it. The general form of a pointer variable declaration is:

```
type *var-name;
```

Here, **type** is the pointer's base type; it must be a valid C++ type and **var-name** is the name of the pointer variable. The asterisk you used to declare a pointer is the same asterisk that you use for multiplication. However, in this

statement the asterisk is being used to designate a variable as a pointer. Following are the valid pointer declaration:

```
int    *ip;    // pointer to an integer
double *dp;    // pointer to a double
float  *fp;    // pointer to a float
char   *ch     // pointer to character
```

The actual data type of the value of all pointers, whether integer, float, character, or otherwise, is the same, a long hexadecimal number that represents a memory address. The only difference between pointers of different data types is the data type of the variable or constant that the pointer points to.

Using Pointers in C++:

There are few important operations, which we will do with the pointers very frequently. **(a)** we define a pointer variables **(b)** assign the address of a variable to a pointer and **(c)** finally access the value at the address available in the pointer variable. This is done by using unary operator `*` that returns the value of the variable located at the address specified by its operand. Following example makes use of these operations:

```
#include <iostream>

using namespace std;

int main ()
{
    int var = 20; // actual variable declaration.
    int *ip; // pointer variable

    ip = &var;      // store address of var in pointer variable

    cout << "Value of var variable: ";
    cout << var << endl;

    // print the address stored in ip pointer variable
    cout << "Address stored in ip variable: ";
    cout << ip << endl;

    // access the value at the address available in
    // pointer
    cout << "Value of *ip variable: ";
    cout << *ip << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces result something as follows:

```
Value of var variable: 20
Address stored in ip variable: 0xbfc601ac
Value of *ip variable: 20
```

C++ Pointers in Detail:

Pointers have many but easy concepts and they are very important to C++ programming. There are following few important pointer concepts which should be clear to a C++ programmer:

Concept	Description
<u>C++ Null Pointers</u>	C++ supports null pointer, which is a constant with a value of zero

	defined in several standard libraries.
C++ pointer arithmetic	There are four arithmetic operators that can be used on pointers: ++, --, +, -
C++ pointers vs arrays	There is a close relationship between pointers and arrays. Let us check how?
C++ array of pointers	You can define arrays to hold a number of pointers.
C++ pointer to pointer	C++ allows you to have pointer on a pointer and so on.
Passing pointers to functions	Passing an argument by reference or by address both enable the passed argument to be changed in the calling function by the called function.
Return pointer from functions	C++ allows a function to return a pointer to local variable, static variable and dynamically allocated memory as well.

C++ Null Pointers

It is always a good practice to assign the pointer NULL to a pointer variable in case you do not have exact address to be assigned. This is done at the time of variable declaration. A pointer that is assigned NULL is called a **null** pointer.

The NULL pointer is a constant with a value of zero defined in several standard libraries, including iostream. Consider the following program:

```
#include <iostream>
using namespace std;

int main ()
{
    int *ptr = NULL;

    cout << "The value of ptr is " << ptr ;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
The value of ptr is 0
```

On most of the operating systems, programs are not permitted to access memory at address 0 because that memory is reserved by the operating system. However, the memory address 0 has special significance; it signals that the pointer is not intended to point to an accessible memory location. But by convention, if a pointer contains the null (zero) value, it is assumed to point to nothing.

To check for a null pointer you can use an if statement as follows:

```
if(ptr)      // succeeds if p is not null
if(!ptr)     // succeeds if p is null
```

Thus, if all unused pointers are given the null value and you avoid the use of a null pointer, you can avoid the accidental misuse of an uninitialized pointer. Many times, uninitialized variables hold some junk values and it becomes difficult to debug the program.

C++ Pointer Arithmetic

As you understood pointer is an address which is a numeric value; therefore, you can perform arithmetic operations on a pointer just as you can a numeric value. There are four arithmetic operators that can be used on pointers: ++, --, +, and -

To understand pointer arithmetic, let us consider that **ptr** is an integer pointer which points to the address 1000. Assuming 32-bit integers, let us perform the following arithmetic operation on the pointer:

```
ptr++
```

the **ptr** will point to the location 1004 because each time ptr is incremented, it will point to the next integer. This operation will move the pointer to next memory location without impacting actual value at the memory location. If ptr points to a character whose address is 1000, then above operation will point to the location 1001 because next character will be available at 1001.

Incrementing a Pointer:

We prefer using a pointer in our program instead of an array because the variable pointer can be incremented, unlike the array name which cannot be incremented because it is a constant pointer. The following program increments the variable pointer to access each succeeding element of the array:

```
#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};
    int *ptr;

    // let us have array address in
    // pointer. ptr = var;
    for (int i = 0; i < MAX; i++)
    {
        cout << "Address of var[" << i << "] = ";
        cout << ptr << endl;

        cout << "Value of var[" << i << "] = ";
        cout << *ptr << endl;

        // point to the next location
        ptr++;
    }
    return 0;
}
```

When the above code is compiled and executed, it produces result something as follows:

```
Address of var[0] = 0xbfa088b0
Value of var[0] = 10
Address of var[1] = 0xbfa088b4
Value of var[1] = 100
Address of var[2] = 0xbfa088b8
```

```
Value of var[2] = 200
```

Decrementing a Pointer:

The same considerations apply to decrementing a pointer, which decreases its value by the number of bytes of its data type as shown below:

```
#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};
    int *ptr;

    // let us have address of the last element in pointer.
    ptr = &var[MAX-1];
    for (int i = MAX; i > 0; i--)
    {
        cout << "Address of var[" << i << "] = ";
        cout << ptr << endl;

        cout << "Value of var[" << i << "] = ";
        cout << *ptr << endl;

        // point to the previous location
        ptr--;
    }
    return 0;
}
```

When the above code is compiled and executed, it produces result something as follows:

```
Address of var[3] = 0xbfdb70f8
Value of var[3] = 200
Address of var[2] = 0xbfdb70f4
Value of var[2] = 100
Address of var[1] = 0xbfdb70f0
Value of var[1] = 10
```

Pointer Comparisons

Pointers may be compared by using relational operators, such as ==, <, and >. If p1 and p2 point to variables that are related to each other, such as elements of the same array, then p1 and p2 can be meaningfully compared.

The following program modifies the previous example one by incrementing the variable pointer so long as the address to which it points is either less than or equal to the address of the last element of the array, which is &var[MAX - 1]:

```
#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};
```

```

int *ptr;

// let us have address of the first element in
pointer. ptr = var;
int i = 0;
while ( ptr <= &var[MAX - 1] )
{
    cout << "Address of var[" << i << "] = ";
    cout << ptr << endl;

    cout << "Value of var[" << i << "] = ";
    cout << *ptr << endl;

    // point to the previous location
    ptr++;
    i++;
}
return 0;
}

```

When the above code is compiled and executed, it produces result something as follows:

```

Address of var[0] = 0xbfce42d0
Value of var[0] = 10
Address of var[1] = 0xbfce42d4
Value of var[1] = 100
Address of var[2] = 0xbfce42d8
Value of var[2] = 200

```

C++ Pointers vs Arrays

Pointers and arrays are strongly related. In fact, pointers and arrays are interchangeable in many cases. For example, a pointer that points to the beginning of an array can access that array by using either pointer arithmetic or array-style indexing. Consider the following program:

```

#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};
    int *ptr;

    // let us have array address in
    pointer. ptr = var;
    for (int i = 0; i < MAX; i++)
    {
        cout << "Address of var[" << i << "] = ";
        cout << ptr << endl;

        cout << "Value of var[" << i << "] = ";
        cout << *ptr << endl;

        // point to the next location
        ptr++;
    }
    return 0;
}

```

```
}
```

When the above code is compiled and executed, it produces result something as follows:

```
Address of var[0] = 0xbfa088b0
Value of var[0] = 10
Address of var[1] = 0xbfa088b4
Value of var[1] = 100
Address of var[2] = 0xbfa088b8
Value of var[2] = 200
```

However, pointers and arrays are not completely interchangeable. For example, consider the following program:

```
#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};

    for (int i = 0; i < MAX; i++)
    {
        *var = i;    // This is a correct syntax
        var++;       // This is incorrect.
    }
    return 0;
}
```

It is perfectly acceptable to apply the pointer operator `*` to `var` but it is illegal to modify `var` value. The reason for this is that `var` is a constant that points to the beginning of an array and can not be used as l-value.

Because an array name generates a pointer constant, it can still be used in pointer-style expressions, as long as it is not modified. For example, the following is a valid statement that assigns `var[2]` the value 500:

```
*(var + 2) = 500;
```

Above statement is valid and will compile successfully because `var` is not changed.

C++ Array of Pointers

Before we understand the concept of array of pointers, let us consider the following example, which makes use of an array of 3 integers:

```
#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};

    for (int i = 0; i < MAX; i++)
    {
        cout << "Value of var[" << i << "] = ";
        cout << var[i] << endl;
    }
}
```

```

    }
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Value of var[0] = 10
Value of var[1] = 100
Value of var[2] = 200

```

There may be a situation, when we want to maintain an array, which can store pointers to an int or char or any other data type available. Following is the declaration of an array of pointers to an integer:

```
int *ptr[MAX];
```

This declares **ptr** as an array of MAX integer pointers. Thus, each element in ptr, now holds a pointer to an int value. Following example makes use of three integers which will be stored in an array of pointers as follows:

```

#include <iostream>

using namespace std;
const int MAX = 3;

int main ()
{
    int var[MAX] = {10, 100, 200};
    int *ptr[MAX];

    for (int i = 0; i < MAX; i++)
    {
        ptr[i] = &var[i]; // assign the address of integer.
    }
    for (int i = 0; i < MAX; i++)
    {
        cout << "Value of var[" << i << "] = ";
        cout << *ptr[i] << endl;
    }
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Value of var[0] = 10
Value of var[1] = 100
Value of var[2] = 200

```

You can also use an array of pointers to character to store a list of strings as follows:

```

#include <iostream>

using namespace std;
const int MAX = 4;

int main ()
{
    char *names[MAX] = {
        "Zara Ali",
        "Hina Ali",
        "Nuha Ali",
        "Sara Ali",
    }
}

```

```

};

for (int i = 0; i < MAX; i++)
{
    cout << "Value of names[" << i << "] = ";
    cout << names[i] << endl;
}
return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Value of names[0] = Zara Ali
Value of names[1] = Hina Ali
Value of names[2] = Nuha Ali
Value of names[3] = Sara Ali

```

C++ Pointer to Pointer

A pointer to a pointer is a form of multiple indirection or a chain of pointers. Normally, a pointer contains the address of a variable. When we define a pointer to a pointer, the first pointer contains the address of the second pointer, which points to the location that contains the actual value as shown below.

A variable that is a pointer to a pointer must be declared as such. This is done by placing an additional asterisk in front of its name. For example, following is the declaration to declare a pointer to a pointer of type int:

```
int **var;
```

When a target value is indirectly pointed to by a pointer to a pointer, accessing that value requires that the asterisk operator be applied twice, as is shown below in the example:

```

#include <iostream>

using namespace std;

int main ()
{
    int var; int
    *ptr; int
    **pptr;

    var = 3000;

    // take the address of var
    ptr = &var;

    // take the address of ptr using address of operator &
    pptr = &ptr;

    // take the value using pptr
    cout << "Value of var :" << var << endl;
    cout << "Value available at *ptr :" << *ptr << endl;
    cout << "Value available at **pptr :" << **pptr << endl;
}

```

```
    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Value of var :3000
Value available at *ptr :3000
Value available at **pptr :3000
```

Passing Pointers to Functions

C++ allows you to pass a pointer to a function. To do so, simply declare the function parameter as a pointer type.

Following a simple example where we pass an unsigned long pointer to a function and change the value inside the function which reflects back in the calling function:

```
#include <iostream>
#include <ctime>

using namespace std;
void getSeconds(unsigned long *par);

int main ()
{
    unsigned long sec;

    getSeconds( &sec );

    // print the actual value
    cout << "Number of seconds :" << sec << endl;

    return 0;
}

void getSeconds(unsigned long *par)
{
    // get the current number of seconds
    *par = time( NULL );
    return;
}
```

When the above code is compiled and executed, it produces the following result:

```
Number of seconds :1294450468
```

The function which can accept a pointer, can also accept an array as shown in the following example:

```
#include <iostream>
using namespace std;

// function declaration:
double getAverage(int *arr, int size);

int main ()
{
    // an int array with 5 elements.
    int balance[5] = {1000, 2, 3, 17, 50};
```

```

double avg;

// pass pointer to the array as an argument.
avg = getAverage( balance, 5 );

// output the returned value
cout << "Average value is: " << avg << endl;

return 0;
}

double getAverage(int *arr, int size)
{
    int i, sum = 0;
    double avg;

    for (i = 0; i < size; ++i)
    {
        sum += arr[i];
    }

    avg = double(sum) / size;

    return avg;
}

```

When the above code is compiled together and executed, it produces the following result:

```
Average value is: 214.4
```

Return Pointer from Functions

As we have seen in last chapter how C++ allows to return an array from a function, similar way C++ allows you to return a pointer from a function. To do so, you would have to declare a function returning a pointer as in the following example:

```

int * myFunction( )
{
    .
    .
    .
}

```

Second point to remember is that, it is not good idea to return the address of a local variable to outside of the function so you would have to define the local variable as **static** variable.

Now consider the following function which will generate 10 random numbers and return them using an array name which represents a pointer ie address of first array element.

```

#include <iostream>
#include <ctime>

using namespace std;

// function to generate and retrun random
numbers. int * getRandom( )
{
    static int r[10];

    // set the seed

```

```

srand( (unsigned)time( NULL ) );
for (int i = 0; i < 10; ++i)
{
    r[i] = rand();
    cout << r[i] << endl;
}

return r;
}

// main function to call above defined
function. int main ()
{
    // a pointer to an
    int. int *p;

    p = getRandom();
    for ( int i = 0; i < 10; i++ )
    {
        cout << "(p + " << i << " ) : ";
        cout << *(p + i) << endl;
    }

    return 0;
}

```

When the above code is compiled together and executed, it produces result something as follow s:

```

624723190
1468735695
807113585
976495677
613357504
1377296355
1530315259
1778906708
1820354158
667126415
*(p + 0) : 624723190
*(p + 1) : 1468735695
*(p + 2) : 807113585
*(p + 3) : 976495677
*(p + 4) : 613357504
*(p + 5) : 1377296355
*(p + 6) : 1530315259
*(p + 7) : 1778906708
*(p + 8) : 1820354158
*(p + 9) : 667126415

```

References

A reference variable is an alias, that is, another name for an already existing variable. Once a reference is initialized with a variable, either the variable name or the reference name may be used to refer to the variable.

C++ References vs Pointers:

References are often confused with pointers but three major differences between references and pointers are:

- You cannot have NULL references. You must always be able to assume that a reference is connected to a legitimate piece of storage.
- Once a reference is initialized to an object, it cannot be changed to refer to another object. Pointers can be pointed to another object at any time.
- A reference must be initialized when it is created. Pointers can be initialized at any time.

Creating References in C++:

Think of a variable name as a label attached to the variable's location in memory. You can then think of a reference as a second label attached to that memory location. Therefore, you can access the contents of the variable through either the original variable name or the reference. For example, suppose we have the following example:

```
int    i = 17;
```

We can declare reference variables for i as follows.

```
int&    r = i;
```

Read the & in these declarations as **reference**. Thus, read the first declaration as "r is an integer reference initialized to i" and read the second declaration as "s is a double reference initialized to d.". Following example makes use of references on int and double:

```
#include <iostream>

using namespace std;

int main ()
{
    // declare simple variables
```

```

int    i;
double d;

// declare reference variables
int&    r = i;
double& s = d;

i = 5;
cout << "Value of i : " << i << endl;
cout << "Value of i reference : " << r << endl;

d = 11.7;
cout << "Value of d : " << d << endl;
cout << "Value of d reference : " << s << endl;

return 0;
}

```

When the above code is compiled together and executed, it produces the following result:

```

Value of i : 5
Value of i reference : 5
Value of d : 11.7
Value of d reference : 11.7

```

References are usually used for function argument lists and function return values. So following are two important subjects related to C++ references which should be clear to a C++ programmer:

Concept	Description
<u>References as parameters</u>	C++ supports passing references as function parameter more safely than parameters.
<u>Reference as return value</u>	You can return reference from a C++ function like a any other data type can be returned.

References as Parameters

We have discussed how we implement **call by reference** concept using pointers. Here is another example of call by reference which makes use of C++ reference:

```

#include <iostream>
using namespace std;

// function declaration
void swap(int& x, int& y);

int main ()
{
    // local variable
    declaration: int a = 100;
    int b = 200;

    cout << "Before swap, value of a : " << a << endl;
    cout << "Before swap, value of b : " << b << endl;

    /* calling a function to swap the
    values.*/ swap(a, b);

    cout << "After swap, value of a : " << a << endl;
}

```

```

    cout << "After swap, value of b :" << b << endl;

    return 0;
}

// function definition to swap the values.
void swap(int& x, int& y)
{
    int temp;
    temp = x; /* save the value at address x
    */ x = y; /* put y into x */
    y = temp; /* put x into y */

    return;
}

```

When the above code is compiled and executed, it produces the following result:

```

Before swap, value of a :100
Before swap, value of b :200
After swap, value of a :200
After swap, value of b :100

```

Reference as Return Value

A C++ program can be made easier to read and maintain by using references rather than pointers. A C++ function can return a reference in a similar way as it returns a pointer.

When a function returns a reference, it returns an implicit pointer to its return value. This way, a function can be used on the left side of an assignment statement. For example, consider this simple program:

```

#include <iostream>
#include <ctime>

using namespace std;

double vals[] = {10.1, 12.6, 33.1, 24.1, 50.0};

double& setValues( int i )
{
    return vals[i];    // return a reference to the ith element
}

// main function to call above defined
function. int main ()
{
    cout << "Value before change" <<
    endl; for ( int i = 0; i < 5; i++ )
    {
        cout << "vals[" << i << " ] =
        "; cout << vals[i] << endl;
    }

    setValues(1) = 20.23; // change 2nd element
    setValues(3) = 70.8; // change 4th element

    cout << "Value after change" << endl;
    for ( int i = 0; i < 5; i++ )

```

```

{
    cout << "vals[" << i << "] = ";
    cout << vals[i] << endl;
}
return 0;
}

```

When the above code is compiled together and executed, it produces the following result:

```

Value before change
vals[0] = 10.1
vals[1] = 12.6
vals[2] = 33.1
vals[3] = 24.1
vals[4] = 50
Value after change
vals[0] = 10.1
vals[1] = 20.23
vals[2] = 33.1
vals[3] = 70.8
vals[4] = 50

```

When returning a reference, be careful that the object being referred to does not go out of scope. So it is not legal to return a reference to local var. But you can always return a reference on a static variable.

```

int& func() {
    int q;
    //! return q; // Compile time error
    static int x;
    return x;      // Safe, x lives outside this scope
}

```

Date and Time

The C++ standard library does not provide a proper date type. C++ inherits the structs and functions for date and time manipulation from C. To access date and time related functions and structures, you would need to include `<ctime>` header file in your C++ program.

There are four time-related types: **clock_t**, **time_t**, **size_t**, and **tm**. The types `clock_t`, `size_t` and `time_t` are capable of representing the system time and date as some sort of integer.

The structure type **tm** holds the date and time in the form of a C structure having the following elements:

```
struct tm {  
    int tm_sec; // seconds of minutes from 0 to 61  
    int tm_min; // minutes of hour from 0 to 59  
    int tm_hour; // hours of day from 0 to 24  
    int tm_mday; // day of month from 1 to 31  
    int tm_mon; // month of year from 0 to 11  
    int tm_year; // year since 1900  
    int tm_wday; // days since sunday  
    int tm_yday; // days since January 1st  
    int tm_isdst; // hours of daylight savings time  
}
```

Following are the important functions, which we use while working with date and time in C or C++. All these functions are part of standard C and C++ library and you can check their detail using reference to C++ standard library given below.

SN	Function & Purpose
1	time_t time(time_t *time); This returns the current calendar time of the system in number of seconds elapsed since January 1, 1970. If the system has no time, .1 is returned.
2	char *ctime(const time_t *time); This returns a pointer to a string of the form <i>day month year hours:minutes:seconds year\n\0</i> .
3	struct tm *localtime(const time_t *time); This returns a pointer to the tm structure representing local time.
4	clock_t clock(void); This returns a value that approximates the amount of time the calling program has been running. A value of .1 is returned if the time is not available.

5	char * asctime (const struct tm * time); This returns a pointer to a string that contains the information stored in the structure pointed to by time converted into the form: day month date hours:minutes.seconds year\n\n0
6	struct tm *gmtime(const time_t *time); This returns a pointer to the time in the form of a tm structure. The time is represented in Coordinated Universal Time (UTC), which is essentially Greenwich Mean Time (GMT).
7	time_t mktime(struct tm *time); This returns the calendar-time equivalent of the time found in the structure pointed to by time.
8	double difftime (time_t time2, time_t time1); This function calculates the difference in seconds between time1 and time2.
9	size_t strftime(); This function can be used to format date and time a specific format.

Current date and time:

Consider you want to retrieve the current system date and time, either as a local time or as a Coordinated Universal Time (UTC). Following is the example to achieve the same:

```
#include <iostream>
#include <ctime>

using namespace std;

int main( )
{
    // current date/time based on current system
    time_t now = time(0);

    // convert now to string form
    char* dt = ctime(&now);

    cout << "The local date and time is: " << dt << endl;

    // convert now to tm struct for
    // UTC
    tm *gmtm = gmtime(&now);
    dt = asctime(gmtm);
    cout << "The UTC date and time is:"<< dt << endl;
}
```

When the above code is compiled and executed, it produces following result:

```
The local date and time is: Sat Jan  8 20:07:41 2011

The UTC date and time is:Sun Jan  9 03:07:41 2011
```

Format time using struct tm:

The **tm** structure is very important while working with date and time in either C or C++. This structure holds the date and time in the form of a C structure as mentioned above. Most of the time related functions makes use of **tm** structure. Following is an example which makes use of various date and time related functions and **tm** structure:

While using structure in this chapter I'm making an assumption that you have basic understanding on C structure and how to access structure members using arrow -> operator.

```
#include <iostream>
```

```

#include <ctime>

using namespace std;

int main( )
{
    // current date/time based on current system
    time_t now = time(0);

    cout << "Number of sec since January 1,1970:" << now << endl;

    tm *ltm = localtime(&now);

    // print various components of tm structure.
    cout << "Year: "<< 1900 + ltm->tm_year << endl;
    cout << "Month: "<< 1 + ltm->tm_mon<< endl;
    cout << "Day: "<< ltm->tm_mday << endl;
    cout << "Time: "<< 1 + ltm->tm_hour <<
    ":"; cout << 1 + ltm->tm_min << ":";
    cout << 1 + ltm->tm_sec << endl;
}

```

When the above code is compiled and executed, it produces the following result:

```

Number of sec since January 1, 1970:1294548238
Year: 2011
Month: 1
Day: 8
Time: 22: 44:59

```

Basic Input/Output

The C++ standard libraries provide an extensive set of input/output capabilities which we will see in

subsequent chapters. This chapter will discuss very basic and most common I/O operations required for C++ programming.

C++ I/O occurs in streams, which are sequences of bytes. If bytes flow from a device like a keyboard, a disk drive, or a network connection, etc., to main memory, this is called **input operation** and if bytes flow from main memory to a device like a display screen, a printer, a disk drive, or a network connection, etc, this is called **output operation**.

I/O Library Header Files:

There are following header files important to C++ programs:

Header File	Function and Description
<iostream>	This file defines the cin , cout , cerr and clog objects, which correspond to the standard input stream, the standard output stream, the un-buffered standard error stream and the buffered standard error stream, respectively.
<iomanip>	This file declares services useful for performing formatted I/O with so-called parameterized stream manipulators, such as setw and setprecision .
<fstream>	This file declares services for user-controlled file processing. We will discuss about it in detail in File and Stream related chapter.

The standard output stream (cout):

The predefined object **cout** is an instance of **ostream** class. The cout object is said to be "connected to" the standard output device, which usually is the display screen. The **cout** is used in conjunction with the stream insertion operator, which is written as << which are two less than signs as shown in the following example.

```
#include <iostream>

using namespace std;

int main( )
{
    char str[] = "Hello C++";

    cout << "Value of str is : " << str << endl;
```

```
}
```

When the above code is compiled and executed, it produces following result:

```
Value of str is : Hello C++
```

The C++ compiler also determines the data type of variable to be output and selects the appropriate stream insertion operator to display the value. The << operator is overloaded to output data items of built-in types integer, float, double, strings and pointer values.

The insertion operator << may be used more than once in a single statement as shown above and **endl** is used to add a new-line at the end of the line.

The standard input stream (cin):

The predefined object **cin** is an instance of **istream** class. The cin object is said to be attached to the standard input device, which usually is the keyboard. The **cin** is used in conjunction with the stream extraction operator, which is written as >> which are two greater than signs as shown in the following example.

```
#include <iostream>

using namespace std;

int main( )
{
    char name[50];

    cout << "Please enter your name: "; cin >> name;
    cout << "Your name is: " << name << endl;
}
```

When the above code is compiled and executed, it will prompt you to enter a name. You enter a value and then hit enter to see the result something as follows:

```
Please enter your name: cplusplus
Your name is: cplusplus
```

The C++ compiler also determines the data type of the entered value and selects the appropriate stream extraction operator to extract the value and store it in the given variables.

The stream extraction operator >> may be used more than once in a single statement. To request more than one datum you can use the following:

```
cin >> name >> age;
```

This will be equivalent to the following two statements:

```
cin >> name;
cin >> age;
```

The standard error stream (cerr):

The predefined object **cerr** is an instance of **ostream** class. The cerr object is said to be attached to the standard error device, which is also a display screen but the object **cerr** is un-buffered and each stream insertion to cerr causes its output to appear immediately.

The **cerr** is also used in conjunction with the stream insertion operator as shown in the following example.

```
#include <iostream>

using namespace std;

int main( )
{
    char str[] = "Unable to read....";

    cerr << "Error message : " << str << endl;
}
```

When the above code is compiled and executed, it produces the following result:

```
Error message : Unable to read....
```

The standard log stream (clog):

The predefined object **clog** is an instance of **ostream** class. The **clog** object is said to be attached to the standard error device, which is also a display screen but the object **clog** is buffered. This means that each insertion to **clog** could cause its output to be held in a buffer until the buffer is filled or until the buffer is flushed.

The **clog** is also used in conjunction with the stream insertion operator as shown in the following example.

```
#include <iostream>

using namespace std;

int main( )
{
    char str[] = "Unable to read....";

    clog << "Error message : " << str << endl;
}
```

When the above code is compiled and executed, it produces the following result:

```
Error message : Unable to read....
```

You would not be able to see any difference in **cout**, **cerr** and **clog** with these small examples, but while writing and executing big programs then difference becomes obvious. So this is good practice to display error messages using **cerr** stream and while displaying other log messages then **clog** should be used.

Data Structures

The C/C++ arrays allow you to define variables that combine several data items of the same kind but **structure** is another user defined data type which allows you to combine data items of different kinds.

Structures are used to represent a record, suppose you want to keep track of your books in a library. You might want to track the following attributes about each book:

- Title
- Author
- Subject
- Book ID

Defining a Structure:

To define a structure, you must use the struct statement. The struct statement defines a new data type, with more than one member, for your program. The format of the struct statement is this:

```
struct [structure tag]
{
    member definition;
    member definition;
    ...
    member definition;
} [one or more structure variables];
```

The **structure tag** is optional and each member definition is a normal variable definition, such as int i; or float f; or any other valid variable definition. At the end of the structure's definition, before the final semicolon, you can specify one or more structure variables but it is optional. Here is the way you would declare the Book structure:

```
struct Books
{
    char title[50];
    char author[50];
    char subject[100];
    int book_id;
}book;
```

Accessing Structure Members:

To access any member of a structure, we use the **member access operator (.)**. The member access operator is coded as a period between the structure variable name and the structure member that we wish to access. You

would use **struct** keyword to define variables of structure type. Following is the example to explain usage of structure:

```
#include <iostream>
#include <cstring>

using namespace std;

struct Books
{
    char title[50];
    char author[50];
    char subject[100];
    int book_id;
};

int main( )
{
    struct Books Book1; // Declare Book1 of type Book struct
    Books Book2; // Declare Book2 of type Book

    // book 1 specification
    strcpy( Book1.title, "Learn C++ Programming");
    strcpy( Book1.author, "Chand Miyan");
    strcpy( Book1.subject, "C++ Programming");
    Book1.book_id = 6495407;

    // book 2 specification
    strcpy( Book2.title, "Telecom
Billing"); strcpy( Book2.author, "Yakit
Singha"); strcpy( Book2.subject,
"Telecom"); Book2.book_id = 6495700;

    // Print Book1 info
    cout << "Book 1 title : " << Book1.title <<endl;
    cout << "Book 1 author : " << Book1.author <<endl;
    cout << "Book 1 subject : " << Book1.subject <<endl;
    cout << "Book 1 id : " << Book1.book_id <<endl;

    // Print Book2 info
    cout << "Book 2 title : " << Book2.title <<endl;
    cout << "Book 2 author : " << Book2.author <<endl;
    cout << "Book 2 subject : " << Book2.subject <<endl;
    cout << "Book 2 id : " << Book2.book_id <<endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Book 1 title : Learn C++ Programming
Book 1 author : Chand Miyan
Book 1 subject : C++ Programming
Book 1 id : 6495407
Book 2 title : Telecom Billing
Book 2 author : Yakrit Singha
Book 2 subject : Telecom
Book 2 id : 6495700
```

Structures as Function Arguments:

You can pass a structure as a function argument in very similar way as you pass any other variable or pointer. You would access structure variables in the similar way as you have accessed in the above example:

```
#include <iostream>
#include <cstring>

using namespace std;
void printBook( struct Books book );

struct Books
{
    char title[50];
    char author[50];
    char subject[100];
    int book_id;
};

int main( )
{
    struct Books Book1; // Declare Book1 of type Book struct
    Books Book2; // Declare Book2 of type Book

    // book 1 specification
    strcpy( Book1.title, "Learn C++ Programming");
    strcpy( Book1.author, "Chand Miyan");
    strcpy( Book1.subject, "C++ Programming");
    Book1.book_id = 6495407;

    // book 2 specification
    strcpy( Book2.title, "Telecom
Billing"); strcpy( Book2.author, "Yakit
Singha"); strcpy( Book2.subject,
"Telecom"); Book2.book_id = 6495700;

    // Print Book1 info
    printBook( Book1 );

    // Print Book2 info
    printBook( Book2 );

    return 0;
}

void printBook( struct Books book )
{
    cout << "Book title : " << book.title <<endl;
    cout << "Book author : " << book.author <<endl;
    cout << "Book subject : " << book.subject <<endl;
    cout << "Book id : " << book.book_id <<endl;
}
```

When the above code is compiled and executed, it produces the following result:

```
Book title : Learn C++ Programming
Book author : Chand Miyan
Book subject : C++ Programming
Book id : 6495407
Book title : Telecom Billing
Book author : Yakıt Singha
```

```
Book subject : Telecom
Book id : 6495700
```

Pointers to Structures:

You can define pointers to structures in very similar way as you define pointer to any other variable as follows:

```
struct Books *struct_pointer;
```

Now, you can store the address of a structure variable in the above defined pointer variable. To find the address of a structure variable, place the & operator before the structure's name as follows:

```
struct_pointer = &Book1;
```

To access the members of a structure using a pointer to that structure, you must use the -> operator as follows:

```
struct_pointer->title;
```

Let us re-write above example using structure pointer, hope this will be easy for you to understand the concept:

```
#include <iostream>
#include <cstring>

using namespace std;
void printBook( struct Books *book );

struct Books
{
    char title[50];
    char author[50];
    char subject[100];
    int book_id;
};

int main( )
{
    struct Books Book1; // Declare Book1 of type Book struct
    Books Book2; // Declare Book2 of type Book

    // Book 1 specification
    strcpy( Book1.title, "Learn C++ Programming");
    strcpy( Book1.author, "Chand Miyan");
    strcpy( Book1.subject, "C++ Programming");
    Book1.book_id = 6495407;

    // Book 2 specification
    strcpy( Book2.title, "Telecom
Billing"); strcpy( Book2.author, "Yakit
Singha"); strcpy( Book2.subject,
"Telecom"); Book2.book_id = 6495700;

    // Print Book1 info, passing address of structure
    printBook( &Book1 );

    // Print Book2 info, passing address of structure
    printBook( &Book2 );

    return 0;
}
// This function accept pointer to structure as parameter.
```

```
void printBook( struct Books *book )
{
    cout << "Book title : " << book->title <<endl; cout
    << "Book author : " << book->author <<endl; cout <<
    "Book subject : " << book->subject <<endl; cout <<
    "Book id : " << book->book_id <<endl;
}
```

When the above code is compiled and executed, it produces the following result:

```
Book title : Learn C++ Programming
Book author : Chand Miyan
Book subject : C++ Programming
Book id : 6495407
Book title : Telecom Billing
Book author : Yakrit Singha
Book subject : Telecom
Book id : 6495700
```

The typedef Keyword

There is an easier way to define structs or you could "alias" types you create. For example:

```
typedef struct
{
    char title[50];
    char author[50];
    char subject[100];
    int book_id;
}Books;
```

Now, you can use *Books* directly to define variables of *Books* type without using struct keyword. Following is the example:

```
Books Book1, Book2;
```

You can use **typedef** keyword for non-structs as well as follows:

```
typedef long int *pint32;

pint32 x, y, z;
```

x, y and z are all pointers to long ints

Classes and Objects

The main purpose of C++ programming is to add object orientation to the C programming language and

classes are the central feature of C++ that supports object-oriented programming and are often called user-defined types.

A class is used to specify the form of an object and it combines data representation and methods for manipulating that data into one neat package. The data and functions within a class are called members of the class.

C++ Class Definitions:

When you define a class, you define a blueprint for a data type. This doesn't actually define any data, but it does define what the class name means, that is, what an object of the class will consist of and what operations can be performed on such an object.

A class definition starts with the keyword **class** followed by the class name; and the class body, enclosed by a pair of curly braces. A class definition must be followed either by a semicolon or a list of declarations. For example, we defined the Box data type using the keyword **class** as follows:

```
class Box
{
    public:
        double length; // Length of a box
        double breadth; // Breadth of a box
        double height; // Height of a box
};
```

The keyword **public** determines the access attributes of the members of the class that follow it. A public member can be accessed from outside the class anywhere within the scope of the class object. You can also specify the members of a class as **private** or **protected** which we will discuss in a sub-section.

Define C++ Objects:

A class provides the blueprints for objects, so basically an object is created from a class. We declare objects of a class with exactly the same sort of declaration that we declare variables of basic types. Following statements declare two objects of class Box:

```
Box Box1; // Declare Box1 of type Box
Box Box2; // Declare Box2 of type Box
```

Both of the objects Box1 and Box2 will have their own copy of data members.

Accessing the Data Members:

The public data members of objects of a class can be accessed using the direct member access operator (.). Let us try following example to make the things clear:

```
#include <iostream>

using namespace std;

class Box
{
public:
    double length; // Length of a box
    double breadth; // Breadth of a box
    double height; // Height of a box
};

int main( )
{
    Box Box1; // Declare Box1 of type Box
    Box2; // Declare Box2 of type Box
    double volume = 0.0; // Store the volume of a box here

    // box 1 specification
    Box1.height = 5.0;
    Box1.length = 6.0;
    Box1.breadth = 7.0;

    // box 2 specification
    Box2.height = 10.0;
    Box2.length = 12.0;
    Box2.breadth = 13.0;
    // volume of box 1
    volume = Box1.height * Box1.length * Box1.breadth;
    cout << "Volume of Box1 : " << volume << endl;

    // volume of box 2
    volume = Box2.height * Box2.length *
    Box2.breadth; cout << "Volume of Box2 : " <<
    volume << endl; return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Volume of Box1 : 210
Volume of Box2 : 1560
```

It is important to note that private and protected members can not be accessed directly using direct member access operator (.). We will learn how private and protected members can be accessed.

Classes & Objects in Detail:

So far, you have got very basic idea about C++ Classes and Objects. There are further interesting concepts related to C++ Classes and Objects which we will discuss in various sub-sections listed below:

Concept	Description

<u>Class member functions</u>	A member function of a class is a function that has its definition or its prototype within the class definition like any other variable.
<u>Class access modifiers</u>	A class member can be defined as public, private or protected. By default members would be assumed as private.
<u>Constructor & destructor</u>	A class constructor is a special function in a class that is called when a new object of the class is created. A destructor is also a special function which is called when created object is deleted.
<u>C++ copy constructor</u>	The copy constructor is a constructor which creates an object by initializing it with an object of the same class, which has been created previously.
<u>C++ friend functions</u>	A friend function is permitted full access to private and protected members of a class.
<u>C++ inline functions</u>	With an inline function, the compiler tries to expand the code in the body of the function in place of a call to the function.
<u>The this pointer in C++</u>	Every object has a special pointer this which points to the object itself.
<u>Pointer to C++ classes</u>	A pointer to a class is done exactly the same way a pointer to a structure is. In fact a class is really just a structure with functions in it.
<u>Static members of a class</u>	Both data members and function members of a class can be declared as static.

Class Member Functions

A member function of a class is a function that has its definition or its prototype within the class definition like any other variable. It operates on any object of the class of which it is a member, and has access to all the members of a class for that object.

Let us take previously defined class to access the members of the class using a member function instead of directly accessing them:

```
class Box
{
    public:

        double length;           // Length of a box

        double breadth;         // Breadth of a box

        double height;          // Height of a box

        double getVolume(void); // Returns box volume
};
```

Member functions can be defined within the class definition or separately using **scope resolution operator**, **::**. Defining a member function within the class definition declares the function **inline**, even if you do not use the inline specifier. So either you can define **Volume()** function as below:

```

class Box
{
    public:

        double length;        // Length of a box
        double breadth;       // Breadth of a box
        double height;        // Height of a box

        double getVolume(void)
        {
            return length * breadth * height;
        }
};

```

If you like you can define same function outside the class using **scope resolution operator**, :: as follows:

```

double Box::getVolume(void)
{
    return length * breadth * height;
}

```

Here, only important point is that you would have to use class name just before :: operator. A member function will be called using a dot operator (.) on a object where it will manipulate data related to that object only as follows:

```

Box myBox;                // Create an object

myBox.getVolume();        // Call member function for the object

```

Let us put above concepts to set and get the value of different class members in a class:

```

#include <iostream>

using namespace std;

class Box
{
    public:

        double length;        // Length of a box
        double breadth;       // Breadth of a box

```

```
double height;                // Height of a box

// Member functions declaration
double getVolume(void);

void setLength( double len );

void setBreadth( double bre );

void setHeight( double hei );
};

// Member functions definitions
double Box::getVolume(void)
{
    return length * breadth * height;
}

void Box::setLength( double len )
{
    length = len;
}

void Box::setBreadth( double bre )
{
    breadth = bre;
}

void Box::setHeight( double hei )
{
    height = hei;
}

// Main function for the program
int main( )
{
```

```

Box Box1;           // Declare Box1 of type Box
Box Box2;           // Declare Box2 of type Box
double volume = 0.0; // Store the volume of a box here

// box 1 specification
Box1.setLength(6.0);
Box1.setBreadth(7.0);
Box1.setHeight(5.0);

// box 2 specification
Box2.setLength(12.0);
Box2.setBreadth(13.0);
Box2.setHeight(10.0);

// volume of box 1
volume = Box1.getVolume();
cout << "Volume of Box1 : " << volume <<endl;

// volume of box 2
volume = Box2.getVolume();

cout << "Volume of Box2 : " << volume
<<endl; return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Volume of Box1 : 210
Volume of Box2 : 1560

```

Class Access Modifiers

Data hiding is one of the important features of Object Oriented Programming which allows preventing the functions of a program to access directly the internal representation of a class type. The access restriction to the class members is specified by the labeled **public**, **private**, and **protected** sections within the class body. The keywords public, private, and protected are called access specifiers.

A class can have multiple public, protected, or private labeled sections. Each section remains in effect until either another section label or the closing right brace of the class body is seen. The default access for members and classes is private.

```

class Base {
    public:

    // public members go here

    protected:

    // protected members go here

    private:

    // private members go here

};

```

The public members:

A **public** member is accessible from anywhere outside the class but within a program. You can set and get the value of public variables without any member function as shown in the following example:

```

#include <iostream>

using namespace std;

class Line
{
    public:
        double length;
        void setLength( double len );
        double getLength( void );
};

// Member functions definitions
double Line::getLength(void)
{
    return length ;
}

void Line::setLength( double len )
{
    length = len;
}

// Main function for the program
int main( )
{
    Line line;

    // set line length
    line.setLength(6.0);
    cout << "Length of line : " << line.getLength() <<endl;

    // set line length without member function
    line.length = 10.0; // OK: because length is public
    cout << "Length of line : " << line.length <<endl;
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
Length of line : 6
Length of line : 10
```

The private members:

A **private** member variable or function cannot be accessed, or even viewed from outside the class. Only the class and friend functions can access private members.

By default all the members of a class would be private, for example in the following class **width** is a private member, which means until you label a member, it will be assumed a private member:

```
class Box
{
    double width;
public:
    double length;
    void setWidth( double wid );
    double getWidth( void );
};
```

Practically, we define data in private section and related functions in public section so that they can be called from outside of the class as shown in the following program.

```
#include <iostream>

using namespace std;

class Box
{
public:
    double length;
    void setWidth( double wid );
    double getWidth( void );

private:
    double width;
};

// Member functions definitions
double Box::getWidth(void)
{
    return width ;
}

void Box::setWidth( double wid )
{
    width = wid;
}

// Main function for the program
int main( )
{
    Box box;

    // set box length without member function box.length
    = 10.0; // OK: because length is public cout <<
    "Length of box : " << box.length <<endl;

    // set box width without member function
```

```

    // box.width = 10.0; // Error: because width is private
    box.setWidth(10.0); // Use member function to set it. cout
    << "Width of box : " << box.getWidth() << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Length of box : 10
Width of box : 10

```

The protected members:

A **protected** member variable or function is very similar to a private member but it provided one additional benefit that they can be accessed in child classes, which are called derived classes.

You will learn derived classes and inheritance in next chapter. For now you can check following example where I have derived one child class **SmallBox** from a parent class **Box**.

Following example is similar to above example and here **width** member will be accessible by any member function of its derived class **SmallBox**.

```

using namespace std;

class Box
{
    protected:
        double width;
};

class SmallBox:Box // SmallBox is the derived class.
{
    public:
        void setSmallWidth( double wid );
        double getSmallWidth( void );
};

// Member functions of child class
double SmallBox::getSmallWidth(void)
{
    return width ;
}

void SmallBox::setSmallWidth( double wid )
{
    width = wid;
}

// Main function for the program
int main( )
{
    SmallBox box;

    // set box width using member
    function box.setSmallWidth(5.0);
    cout << "Width of box : "<< box.getSmallWidth() << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
Width of box : 5
```

Constructor & Destructor

The Class Constructor:

A class **constructor** is a special member function of a class that is executed whenever we create new objects of that class.

A constructor will have exact same name as the class and it does not have any return type at all, not even void. Constructors can be very useful for setting initial values for certain member variables.

Following example explains the concept of constructor:

```
#include <iostream>

using namespace std;

class Line
{
public:
    void setLength( double len );
    double getLength( void );
    Line(); // This is the constructor

private:
    double length;
};

// Member functions definitions including
// constructor Line::Line(void)
{
    cout << "Object is being created" << endl;
}

void Line::setLength( double len )
{
    length = len;
}

double Line::getLength( void )
{
    return length;
}

// Main function for the program
int main( )
{
    Line line;

    // set line length
    line.setLength(6.0);
    cout << "Length of line : " << line.getLength() << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Object is being created
Length of line : 6
```

Parameterized Constructor:

A default constructor does not have any parameter, but if you need, a constructor can have parameters. This helps you to assign initial value to an object at the time of its creation as shown in the following example:

```
#include <iostream>

using namespace std;

class Line
{
public:
    void setLength( double len );
    double getLength( void );
    Line(double len); // This is the constructor

private:
    double length;
};

// Member functions definitions including
// constructor Line::Line( double len)
{
    cout << "Object is being created, length = " << len <<
    endl; length = len;
}

void Line::setLength( double len )
{
    length = len;
}

double Line::getLength( void )
{
    return length;
}

// Main function for the program
int main( )
{
    Line line(10.0);

    // get initially set length.
    cout << "Length of line : " << line.getLength()
    <<endl; // set line length again
    line.setLength(6.0);
    cout << "Length of line : " << line.getLength() <<endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Object is being created, length = 10
Length of line : 10
Length of line : 6
```

Using Initialization Lists to Initialize Fields:

In case of parameterized constructor, you can use following syntax to initialize the fields:

```
Line::Line( double len): length(len)
{
    cout << "Object is being created, length = " << len << endl;
}
```

Above syntax is equal to the following syntax:

```
Line::Line( double len)
{
    cout << "Object is being created, length = " << len <<
    endl; length = len;
}
```

If for a class C, you have multiple fields X, Y, Z, etc., to be initialized, then use can use same syntax and separate the fields by comma as follows:

```
C::C( double a, double b, double c): X(a), Y(b), Z(c)
{
    ....
}
```

The Class Destructor:

A **destructor** is a special member function of a class that is executed whenever an object of its class goes out of scope or whenever the delete expression is applied to a pointer to the object of that class.

A destructor will have exact same name as the class prefixed with a tilde (~) and it can neither return a value nor can it take any parameters. Destructor can be very useful for releasing resources before coming out of the program like closing files, releasing memories etc.

Following example explains the concept of destructor:

```
#include <iostream>

using namespace std;

class Line
{
public:
    void setLength( double len );
    double getLength( void );
    Line(); // This is the constructor declaration
    ~Line(); // This is the destructor: declaration

private:
    double length;
};

// Member functions definitions including
// constructor Line::Line(void)
{
    cout << "Object is being created" << endl;
}
Line::~~Line(void)
{
    cout << "Object is being deleted" << endl;
}
```

```

}

void Line::setLength( double len )
{
    length = len;
}

double Line::getLength( void )
{
    return length;
}

// Main function for the program
int main( )
{
    Line line;

    // set line length
    line.setLength(6.0);
    cout << "Length of line : " << line.getLength() <<endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Object is being created
Length of line : 6
Object is being deleted

```

C++ Copy Constructor

The **copy constructor** is a constructor which creates an object by initializing it with an object of the same class, which has been created previously. The copy constructor is used to:

- Initialize one object from another of the same type.
- Copy an object to pass it as an argument to a function.
- Copy an object to return it from a function.

If a copy constructor is not defined in a class, the compiler itself defines one. If the class has pointer variables and has some dynamic memory allocations, then it is a must to have a copy constructor. The most common form of copy constructor is shown here:

```

classname (const classname &obj) {
    // body of constructor
}

```

Here, **obj** is a reference to an object that is being used to initialize another object.

```

#include <iostream>

using namespace std;

class Line
{
public:

```

```

    int getLength( void );
    Line( int len );           // simple constructor
    Line( const Line &obj);    // copy constructor
    ~Line();                   // destructor

private:
    int *ptr;
};

// Member functions definitions including
// constructor Line::Line(int len)
{
    cout << "Normal constructor allocating ptr" <<
    endl; // allocate memory for the pointer;
    ptr = new int;
    *ptr = len;
}

Line::Line(const Line &obj)
{
    cout << "Copy constructor allocating ptr." <<
    endl; ptr = new int;
    *ptr = *obj.ptr; // copy the value
}

Line::~~Line(void)
{
    cout << "Freeing memory!" <<
    endl; delete ptr;
}

int Line::getLength( void )
{
    return *ptr;
}

void display(Line obj)
{
    cout << "Length of line : " << obj.getLength() <<endl;
}

// Main function for the program
int main( )
{
    Line line(10);

    display(line);

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Normal constructor allocating ptr
Copy constructor allocating ptr.
Length of line : 10
Freeing memory!
Freeing memory!

```

Let us see the same example but with a small change to create another object using existing object of the same type:

```

#include <iostream>

using namespace std;

class Line
{
public:
    int getLength( void );
    Line( int len );           // simple constructor
    Line( const Line &obj);    // copy constructor
    ~Line();                   // destructor

private:
    int *ptr;
};

// Member functions definitions including
// constructor Line::Line(int len)
{
    cout << "Normal constructor allocating ptr" <<
    endl; // allocate memory for the pointer;
    ptr = new int;
    *ptr = len;
}

Line::Line(const Line &obj)
{
    cout << "Copy constructor allocating ptr." <<
    endl; ptr = new int;
    *ptr = *obj.ptr; // copy the value
}

Line::~~Line(void)
{
    cout << "Freeing memory!" <<
    endl; delete ptr;
}

int Line::getLength( void )
{
    return *ptr;
}

void display(Line obj)
{
    cout << "Length of line : " << obj.getLength() <<endl;
}

// Main function for the program
int main( )
{
    Line line1(10);

    Line line2 = line1; // This also calls copy constructor

    display(line1);
    display(line2);

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
Normal constructor allocating ptr
Copy constructor allocating ptr.
Copy constructor allocating ptr.
Length of line : 10
Freeing memory!
Copy constructor allocating ptr.
Length of line : 10
Freeing memory!
Freeing memory!
Freeing memory!
```

C++ Friend Functions

A friend function of a class is defined outside that class' scope but it has the right to access all private and protected members of the class. Even though the prototypes for friend functions appear in the class definition, friends are not member functions.

A friend can be a function, function template, or member function, or a class or class template, in which case the entire class and all of its members are friends.

To declare a function as a friend of a class, precede the function prototype in the class definition with keyword **friend** as follows:

```
class Box
{
    double
width; public:
    double length;
    friend void printWidth( Box box );
    void setWidth( double wid );
};
```

To declare all member functions of class ClassTwo as friends of class ClassOne, place a following declaration in the definition of class ClassOne:

```
friend class ClassTwo;
```

Consider the following program:

```
#include <iostream>

using namespace std;

class Box
{
    double
width; public:
    friend void printWidth( Box box );
    void setWidth( double wid );
};

// Member function definition
void Box::setWidth( double wid )
{
    width = wid;
}

// Note: printWidth() is not a member function of any class.
```

```

void printWidth( Box box )
{
    /* Because setWidth() is a friend of Box, it can
       directly access any member of this class */
    cout << "Width of box : " << box.width << endl;
}

// Main function for the program
int main( )
{
    Box box;

    // set box width without member
    function box.setWidth(10.0);

    // Use friend function to print the width.
    printWidth( box );

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Width of box : 10

```

C++ Inline Functions

C++ **inline** function is a powerful concept that is commonly used with classes. If a function is inline, the compiler places a copy of the code of that function at each point where the function is called at compile time.

Any change to an inline function could require all clients of the function to be recompiled because the compiler would need to replace all the code once again otherwise it will continue with old functionality.

To inline a function, place the keyword **inline** before the function name and define the function before any calls are made to the function. The compiler can ignore the inline qualifier in case the defined function is more than a line.

A function definition in a class definition is an inline function definition, even without the use of the **inline** specifier.

Following is an example, which makes use of inline function to return max of two numbers:

```

#include <iostream>

using namespace std;

inline int Max(int x, int y)
{
    return (x > y)? x : y;
}

// Main function for the program
int main( )
{
    cout << "Max (20,10): " << Max(20,10) << endl;
    cout << "Max (0,200): " << Max(0,200) << endl;
    cout << "Max (100,1010): " << Max(100,1010) << endl;
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
Max (20,10): 20
Max (0,200): 200
Max (100,1010): 1010
```

The this Pointer in C++

Every object in C++ has access to its own address through an important pointer called **this** pointer. The **this** pointer is an implicit parameter to all member functions. Therefore, inside a member function, this may be used to refer to the invoking object.

Friend functions do not have a **this** pointer, because friends are not members of a class. Only member functions have a **this** pointer.

Let us try the following example to understand the concept of this pointer:

```
#include <iostream>

using namespace std;

class Box
{
public:
    // Constructor definition
    Box(double l=2.0, double b=2.0, double h=2.0)
    {
        cout << "Constructor called." <<
        endl; length = l;
        breadth = b;
        height = h;
    }
    double Volume()
    {
        return length * breadth * height;
    }
    int compare(Box box)
    {
        return this->Volume() > box.Volume();
    }
private:
    double length;    // Length of a box
    double breadth;    // Breadth of a box
    double height;    // Height of a box
};

int main(void)
{
    Box Box1(3.3, 1.2, 1.5);    // Declare box1
    Box Box2(8.5, 6.0, 2.0);    // Declare box2

    if(Box1.compare(Box2))
    {
        cout << "Box2 is smaller than Box1" << endl;
    }
    else
    {
        cout << "Box2 is equal to or larger than Box1" << endl;
    }
    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Constructor called.  
Constructor called.  
Box2 is equal to or larger than Box1
```

Pointer to C++ Classes

A pointer to a C++ class is done exactly the same way as a pointer to a structure and to access members of a pointer to a class you use the member access operator `->` operator, just as you do with pointers to structures. Also as with all pointers, you must initialize the pointer before using it.

Let us try the following example to understand the concept of pointer to a class:

```
#include <iostream>  
  
using namespace std;  
  
class Box  
{  
    public:  
        // Constructor definition  
        Box(double l=2.0, double b=2.0, double h=2.0)  
        {  
            cout << "Constructor called." <<  
                endl; length = l;  
            breadth = b;  
            height = h;  
        }  
        double Volume()  
        {  
            return length * breadth * height;  
        }  
    private:  
        double length;    // Length of a box  
        double breadth;   // Breadth of a box  
        double height;    // Height of a box  
};  
  
int main(void)  
{  
    Box Box1(3.3, 1.2, 1.5);    // Declare box1  
    Box Box2(8.5, 6.0, 2.0);    // Declare box2  
    Box *ptrBox;                // Declare pointer to a class.  
  
    // Save the address of first  
    object ptrBox = &Box1;  
  
    // Now try to access a member using member access operator  
    cout << "Volume of Box1: " << ptrBox->Volume() << endl;  
  
    // Save the address of first object  
    ptrBox = &Box2;  
  
    // Now try to access a member using member access operator  
    cout << "Volume of Box2: " << ptrBox->Volume() << endl;  
  
    return 0;  
}
```

When the above code is compiled and executed, it produces the following result:

```
Constructor called.  
Constructor called.  
Volume of Box1: 5.94  
Volume of Box2: 102
```

Static Members of a Class

We can define class members static using **static** keyword. When we declare a member of a class as static it means no matter how many objects of the class are created, there is only one copy of the static member.

A static member is shared by all objects of the class. All static data is initialized to zero when the first object is created, if no other initialization is present. We can't put it in the class definition but it can be initialized outside the class as done in the following example by redeclaring the static variable, using the scope resolution operator `::` to identify which class it belongs to.

Let us try the following example to understand the concept of static data members:

```
#include <iostream>

using namespace std;

class Box
{
public:
    static int objectCount; //
    Constructor definition
    Box(double l=2.0, double b=2.0, double h=2.0)
    {
        cout << "Constructor called." <<
        endl; length = l;
        breadth = b;
        height = h;
        // Increase every time object is
        created objectCount++;
    }
    double Volume()
    {
        return length * breadth * height;
    }
private:
    double length;    // Length of a box
    double breadth;   // Breadth of a box
    double height;    // Height of a box
};

// Initialize static member of class
Box int Box::objectCount = 0;

int main(void)
{
    Box Box1(3.3, 1.2, 1.5);    // Declare box1
    Box Box2(8.5, 6.0, 2.0);    // Declare box2

    // Print total number of objects.
    cout << "Total objects: " << Box::objectCount << endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Constructor called.  
Constructor called.  
Total objects: 2
```

Static Function Members:

By declaring a function member as static, you make it independent of any particular object of the class. A static member function can be called even if no objects of the class exist and the **static** functions are accessed using only the class name and the scope resolution operator ::.

A static member function can only access static data member, other static member functions and any other functions from outside the class.

Static member functions have a class scope and they do not have access to the **this** pointer of the class. You could use a static member function to determine whether some objects of the class have been created or not.

Let us try the following example to understand the concept of static function members:

```
#include <iostream>

using namespace std;

class Box
{
public:
    static int objectCount; //
    Constructor definition
    Box(double l=2.0, double b=2.0, double h=2.0)
    {
        cout << "Constructor called." <<
        endl; length = l;
        breadth = b;
        height = h;
        // Increase every time object is
        created objectCount++;
    }
    double Volume()
    {
        return length * breadth * height;
    }
    static int getCount()
    {
        return objectCount;
    }
private:
    double length;      // Length of a box
    double breadth;     // Breadth of a box
    double height;      // Height of a box
};

// Initialize static member of class
Box int Box::objectCount = 0;

int main(void)
{
    // Print total number of objects before creating object. cout
    << "Initial Stage Count: " << Box::getCount() << endl;

    Box Box1(3.3, 1.2, 1.5);    // Declare box1
```

```
Box Box2(8.5, 6.0, 2.0);    // Declare box2

// Print total number of objects after creating object.
cout << "Final Stage Count: " << Box::getCount() << endl;

return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Initial Stage Count: 0
Constructor called.
Constructor called.
Final Stage Count: 2
```

Inheritance

One of the most important concepts in object-oriented programming is that of inheritance. Inheritance

allows us to define a class in terms of another class, which makes it easier to create and maintain an application. This also provides an opportunity to reuse the code functionality and fast implementation time.

When creating a class, instead of writing completely new data members and member functions, the programmer can designate that the new class should inherit the members of an existing class. This existing class is called the **base** class, and the new class is referred to as the **derived** class.

The idea of inheritance implements the **is a** relationship. For example, mammal IS-A animal, dog IS-A mammal hence dog IS-A animal as well and so on.

Base & Derived Classes:

A class can be derived from more than one classes, which means it can inherit data and functions from multiple base classes. To define a derived class, we use a class derivation list to specify the base class(es). A class derivation list names one or more base classes and has the form:

```
class derived-class: access-specifier base-class
```

Where access-specifier is one of **public**, **protected**, or **private**, and base-class is the name of a previously defined class. If the access-specifier is not used, then it is private by default.

Consider a base class **Shape** and its derived class **Rectangle** as follows:

```
#include <iostream>

using namespace std;

// Base class
class Shape
{
    public:
        void setWidth(int w)
        {
            width = w;
        }
        void setHeight(int h)
        {
            height = h;
        }
    protected:
        int width;
```

```

        int height;
    };

    // Derived class
    class Rectangle: public Shape
    {
    public:
        int getArea()
        {
            return (width * height);
        }
    };

    int main(void)
    {
        Rectangle Rect;

        Rect.setWidth(5);
        Rect.setHeight(7);

        // Print the area of the object.
        cout << "Total area: " << Rect.getArea() << endl;

        return 0;
    }

```

When the above code is compiled and executed, it produces the following result:

```
Total area: 35
```

Access Control and Inheritance:

A derived class can access all the non-private members of its base class. Thus base-class members that should not be accessible to the member functions of derived classes should be declared private in the base class.

We can summarize the different access types according to who can access them in the following way:

Access	Public	protected	private
Same class	Yes	yes	yes
Derived classes	Yes	yes	no
Outside classes	Yes	No	no

A derived class inherits all base class methods with the following exceptions:

- Constructors, destructors and copy constructors of the base class.
- Overloaded operators of the base class.
- The friend functions of the base class.

Type of Inheritance:

When deriving a class from a base class, the base class may be inherited through **public**, **protected** or **private** inheritance. The type of inheritance is specified by the access-specifier as explained above.

We hardly use **protected** or **private** inheritance but **public** inheritance is commonly used. While using different type of inheritance, following rules are applied:

- **Public Inheritance:** When deriving a class from a **public** base class, **public** members of the base class become **public** members of the derived class and **protected** members of the base class become **protected** members of the derived class. A base class's **private** members are never accessible directly from a derived class, but can be accessed through calls to the **public** and **protected** members of the base class.
- **Protected Inheritance:** When deriving from a **protected** base class, **public** and **protected** members of the base class become **protected** members of the derived class.
- **Private Inheritance:** When deriving from a **private** base class, **public** and **protected** members of the base class become **private** members of the derived class.

Multiple Inheritances:

A C++ class can inherit members from more than one class and here is the extended syntax:

```
class derived-class: access baseA, access baseB....
```

Where access is one of **public**, **protected**, or **private** and would be given for every base class and they will be separated by comma as shown above. Let us try the following example:

```
#include <iostream>

using namespace std;

// Base class Shape
class Shape
{
public:
    void setWidth(int w)
    {
        width = w;
    }
    void setHeight(int h)
    {
        height = h;
    }
protected:
    int width;
    int height;
};

// Base class PaintCost
class PaintCost
{
public:
    int getCost(int area)
    {
        return area * 70;
    }
};

// Derived class
class Rectangle: public Shape, public PaintCost
{
public:
    int getArea()
    {
```

```

        return (width * height);
    }
};

int main(void)
{
    Rectangle Rect;
    int area;

    Rect.setWidth(5);
    Rect.setHeight(7);

    area = Rect.getArea();

    // Print the area of the object.
    cout << "Total area: " << Rect.getArea() << endl;

    // Print the total cost of painting
    cout << "Total paint cost: $" << Rect.getCost(area) << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Total area: 35
Total paint cost: $2450

```

Overloading

C++ allows you to specify more than one definition for a **function** name or an **operator** in the same scope, which is called **function overloading** and **operator overloading** respectively.

An overloaded declaration is a declaration that had been declared with the same name as a previously declared declaration in the same scope, except that both declarations have different arguments and obviously different definition (implementation).

When you call an overloaded **function** or **operator**, the compiler determines the most appropriate definition to use by comparing the argument types you used to call the function or operator with the parameter types specified in the definitions. The process of selecting the most appropriate overloaded function or operator is called **overload resolution**.

Function overloading in C++:

You can have multiple definitions for the same function name in the same scope. The definition of the function must differ from each other by the types and/or the number of arguments in the argument list. You can not overload function declarations that differ only by return type.

Following is the example where same function **print()** is being used to print different data types:

```
#include <iostream>
using namespace std;

class printData
{
public:
    void print(int i) {
        cout << "Printing int: " << i << endl;
    }

    void print(double f) {
        cout << "Printing float: " << f << endl;
    }

    void print(char* c) {
        cout << "Printing character: " << c << endl;
    }
};

int main(void)
```

```

{
    printData pd;

    // Call print to print
    integer pd.print(5);
    // Call print to print
    float pd.print(500.263);
    // Call print to print character
    pd.print("Hello C++");

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Printing int: 5
Printing float: 500.263
Printing character: Hello C++

```

Operators overloading in C++:

You can redefine or overload most of the built-in operators available in C++. Thus a programmer can use operators with user-defined types as well.

Overloaded operators are functions with special names the keyword operator followed by the symbol for the operator being defined. Like any other function, an overloaded operator has a return type and a parameter list.

```
Box operator+(const Box&);
```

declares the addition operator that can be used to **add** two Box objects and returns final Box object. Most overloaded operators may be defined as ordinary non-member functions or as class member functions. In case we define above function as non-member function of a class then we would have to pass two arguments for each operand as follows:

```
Box operator+(const Box&, const Box&);
```

Following is the example to show the concept of operator over loading using a member function. Here an object is passed as an argument whose properties will be accessed using this object, the object which will call this operator can be accessed using **this** operator as explained below:

```

#include <iostream>
using namespace std;

class Box
{
public:

    double getVolume(void)
    {
        return length * breadth * height;
    }
    void setLength( double len )
    {
        length = len;
    }

    void setBreadth( double bre )
    {
        breadth = bre;
    }
}

```

```

    }

    void setHeight( double hei )
    {
        height = hei;
    }

    // Overload + operator to add two Box objects.
    Box operator+(const Box& b)
    {
        Box box;
        box.length = this->length + b.length;
        box.breadth = this->breadth +
        b.breadth; box.height = this->height +
        b.height; return box;
    }
private:
    double length;        // Length of a box
    double breadth;       // Breadth of a box
    double height;        // Height of a box
};

// Main function for the program
int main( )
{
    Box Box1;              // Declare Box1 of type Box
    Box Box2;              // Declare Box2 of type Box
    Box Box3;              // Declare Box3 of type Box
    double volume = 0.0;    // Store the volume of a box here

    // box 1 specification
    Box1.setLength(6.0);
    Box1.setBreadth(7.0);
    Box1.setHeight(5.0);

    // box 2 specification
    Box2.setLength(12.0);
    Box2.setBreadth(13.0);
    Box2.setHeight(10.0);

    // volume of box 1
    volume = Box1.getVolume();
    cout << "Volume of Box1 : " << volume <<endl;

    // volume of box 2
    volume = Box2.getVolume();
    cout << "Volume of Box2 : " << volume <<endl;

    // Add two object as follows:
    Box3 = Box1 + Box2;

    // volume of box 3
    volume = Box3.getVolume();
    cout << "Volume of Box3 : " << volume <<endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Volume of Box1 : 210
Volume of Box2 : 1560

```

Overloadable/Non-overloadable Operators:

Following is the list of operators which can be overloaded:

+	-	*	/	%	^
&		~	!	,	=
<	>	<=	>=	++	--
<<	>>	==	!=	&&	
+=	-=	/=	%=	^=	&=
=	*=	<<=	>>=	[]	()
->	->*	new	new []	Delete	delete []

Following is the list of operators, which can not be overloaded:

::	.*	.	?:
----	----	---	----

Operator Overloading Examples:

Here are various operator overloading examples to help you in understanding the concept.

S.N.	Operators and Example
1	Unary operators overloading
2	Binary operators overloading
3	Relational operators overloading
4	Input/Output operators overloading
5	++ and -- operators overloading
6	Assignment operators overloading
7	Function call () operator overloading
8	Subscripting [] operator overloading
9	Class member access operator -> overloading

Unary Operators Overloading

The unary operators operate on a single operand and following are the examples of Unary operators:

- [The increment \(++\) and decrement \(--\) operators.](#)
 - The unary minus (-) operator.
 - The logical not (!) operator.
-

The unary operators operate on the object for which they were called and normally, this operator appears on the left side of the object, as in !obj, -obj, and ++obj but sometime they can be used as postfix as well like obj++ or obj--.

Following example explains how minus (-) operator can be overloaded for prefix as well as postfix usage.

```
#include <iostream>
using namespace std;

class Distance
{
private:
    int feet;           // 0 to infinite
    int inches;         // 0 to 12
public:
    // required constructors
    Distance(){
        feet = 0;
        inches = 0;
    }
    Distance(int f, int i){ feet = f;
        inches = i;
    }
    // method to display distance
    void displayDistance()
    {
        cout << "F: " << feet << " I:" << inches << endl;
    }
    // overloaded minus (-) operator
    Distance operator- ()
    {
        feet = -feet;
        inches = -inches;
        return Distance(feet, inches);
    }
};

int main()
{
    Distance D1(11, 10), D2(-5, 11);

    -D1;
    D1.displayDistance();    // apply negation
                             // display D1

    -D2;
    D2.displayDistance();    // apply negation
                             // display D2

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
F: -11 I:-10
F: 5 I:-11
```

Hope above example makes your concept clear and you can apply similar concept to overload Logical Not Operators (!).

Binary Operators Overloading

The unary operators take two arguments and following are the examples of Binary operators. You use binary operators very frequently like addition (+) operator, subtraction (-) operator and division (/) operator.

Following example explain how addition (+) operator can be overloaded. Similar way, you can overload subtraction (-) and division (/) operators.

```
#include <iostream>
using namespace std;

class Box
{
    double length;    // Length of a box
    double breadth;   // Breadth of a box
    double height;    // Height of a box
public:

    double getVolume(void)
    {
        return length * breadth * height;
    }
    void setLength( double len )
    {
        length = len;
    }

    void setBreadth( double bre )
    {
        breadth = bre;
    }

    void setHeight( double hei )
    {
        height = hei;
    }

    // Overload + operator to add two Box objects.
    Box operator+(const Box& b)
    {
        Box box;
        box.length = this->length + b.length;
        box.breadth = this->breadth +
        b.breadth; box.height = this->height +
        b.height; return box;
    }
};

// Main function for the program
int main( )
{
    Box Box1;           // Declare Box1 of type Box
    Box Box2;           // Declare Box2 of type Box
    Box Box3;           // Declare Box3 of type Box
    double volume = 0.0; // Store the volume of a box here

    // box 1 specification
    Box1.setLength(6.0);
    Box1.setBreadth(7.0);
    Box1.setHeight(5.0);

    // box 2 specification
    Box2.setLength(12.0);
    Box2.setBreadth(13.0);
    Box2.setHeight(10.0);
```

```

// volume of box 1
volume = Box1.getVolume();
cout << "Volume of Box1 : " << volume <<endl;

// volume of box 2
volume = Box2.getVolume();
cout << "Volume of Box2 : " << volume <<endl;

// Add two object as follows:
Box3 = Box1 + Box2;

// volume of box 3
volume = Box3.getVolume();
cout << "Volume of Box3 : " << volume <<endl;

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Volume of Box1 : 210
Volume of Box2 : 1560
Volume of Box3 : 5400

```

Relational Operators Overloading

There are various relational operators supported by C++ language like (<, >, <=, >=, ==, etc.) which can be used to compare C++ built-in data types.

You can overload any of these operators, which can be used to compare the objects of a class.

Following example explain how a < operator can be overloaded and similar way you can overload other relational operators.

```

#include <iostream>
using namespace std;

class Distance
{
private:
    int feet;           // 0 to infinite
    int inches;         // 0 to 12
public:
    // required constructors
    Distance(){
        feet = 0;
        inches = 0;
    }
    Distance(int f, int i){ feet = f; inches = i; }
    // method to display distance
    void displayDistance()
    {
        cout << "F: " << feet << " I:" << inches <<endl;
    }
    // overloaded minus (-) operator

```

```

Distance operator- ()
{
    feet = -feet;
    inches = -inches;
    return Distance(feet, inches);
}
// overloaded < operator
bool operator <(const Distance& d)
{
    if(feet < d.feet)
    {
        return true;
    }
    if(feet == d.feet && inches < d.inches)
    {
        return true;
    }
    return false;
}
};
int main()
{
    Distance D1(11, 10), D2(5, 11);

    if( D1 < D2 )
    {
        cout << "D1 is less than D2 " << endl;
    }
    else
    {
        cout << "D2 is less than D1 " << endl;
    }
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
D2 is less than D1
```

Input/Output Operators Overloading

C++ is able to input and output the built-in data types using the stream extraction operator >> and the stream insertion operator <<. The stream insertion and stream extraction operators also can be overloaded to perform input and output for user-defined types like an object.

Here it is important to make operator overloading function a friend of the class because it would be called without creating an object.

Following example explains how extraction operator >> and insertion operator <<.

```

#include <iostream>
using namespace std;

class Distance
{
private:
    int feet;           // 0 to infinite
    int inches;         // 0 to 12
public:

```

```

// required constructors
Distance(){
    feet = 0;
    inches = 0;
}
Distance(int f, int
i){ feet = f;
    inches = i;
}
friend ostream &operator<<( ostream &output,
                           const Distance &D )
{
    output << "F : " << D.feet << " I : " <<
D.inches; return output;
}

friend istream &operator>>( istream &input, Distance &D )
{
    input >> D.feet >>
D.inches; return input;
}
};
int main()
{
    Distance D1(11, 10), D2(5, 11), D3;

    cout << "Enter the value of object : " << endl;
    cin >> D3;

    cout << "First Distance : " << D1 << endl;
    cout << "Second Distance : " << D2 << endl;
    cout << "Third Distance : " << D3 << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

$./a.out
Enter the value of object :
70 10

First Distance : F : 11 I : 10
Second Distance : F : 5 I : 11
Third Distance : F : 70 I : 10

```

++ and -- Operators Overloading

The increment (++) and decrement (--) operators are two important unary operators available in C++.

Following example explain how increment (++) operator can be overloaded for prefix as well as postfix usage. Similar way you can overload operator (--).

```

#include <iostream>
using namespace std;

class Time
{

```

```

private:
    int hours;           // 0 to 23
    int minutes;         // 0 to 59
public:
    // required constructors
    Time(){
        hours = 0;
        minutes = 0;
    }
    Time(int h, int
        m){ hours = h;
        minutes = m;
    }
    // method to display
    time void displayTime()
    {
        cout << "H: " << hours << " M:" << minutes << endl;
    }
    // overloaded prefix ++ operator
    Time operator++ ( )
    {
        ++minutes; // increment this object
        if(minutes >= 60)
        {
            ++hours;
            minutes -= 60;
        }
        return Time(hours, minutes);
    }
    // overloaded postfix ++ operator
    Time operator++( int )
    {
        // save the original value
        Time T(hours, minutes);
        // increment this
        object ++minutes;
        if(minutes >= 60)
        {
            ++hours;
            minutes -= 60;
        }
        // return old original
        value return T;
    }
};

int main()
{
    Time T1(11, 59), T2(10,40);

    ++T1;           // increment T1
    T1.displayTime(); // display T1
    ++T1;           // increment T1 again
    T1.displayTime(); // display T1

    T2++;           // increment T2
    T2.displayTime(); // display T2
    T2++;           // increment T2 again
    T2.displayTime(); // display T2
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```
H: 12 M:0
H: 12 M:1
H: 10 M:41
H: 10 M:42
```

Assignment Operators Overloading

You can overload the assignment operator (=) just as you can other operators and it can be used to create an object just like the copy constructor.

Following example explain how an assignment operator can be overloaded.

```
#include <iostream>
using namespace std;

class Distance
{
private:
    int feet;           // 0 to infinite
    int inches;         // 0 to 12
public:
    // required constructors
    Distance(){
        feet = 0;
        inches = 0;
    }
    Distance(int f, int i){ feet = f;
        inches = i;
    }
    void operator=(const Distance &D )
    {
        feet = D.feet;
        inches = D.inches;
    }
    // method to display distance
    void displayDistance()
    {
        cout << "F: " << feet << " I:" << inches << endl;
    }
};

int main()
{
    Distance D1(11, 10), D2(5, 11);

    cout << "First Distance : ";
    D1.displayDistance();
    cout << "Second Distance : ";
    D2.displayDistance();

    // use assignment operator
    D1 = D2;
    cout << "First Distance : ";
    D1.displayDistance();

    return 0;
}
```

```
}
```

When the above code is compiled and executed, it produces the following result:

```
First Distance : F: 11 I:10
Second Distance :F: 5 I:11
First Distance :F: 5 I:11
```

Function call- Operator () Overloading

The function call operator () can be overloaded for objects of class type. When you overload (), you are not creating a new way to call a function. Rather, you are creating an operator function that can be passed an arbitrary number of parameters.

Following example explains how a function call operator () can be overloaded.

```
#include <iostream>
using namespace std;

class Distance
{
private:
    int feet;           // 0 to infinite
    int inches;         // 0 to 12
public:
    // required constructors
    Distance(){
        feet = 0;
        inches = 0;
    }
    Distance(int f, int i){ feet = f;
        inches = i;
    }
    // overload function call
    Distance operator()(int a, int b, int c)
    {
        Distance D;
        // just put random calculation
        D.feet = a + c + 10;
        D.inches = b + c + 100;
        return D;
    }
    // method to display distance
    void displayDistance()
    {
        cout << "F: " << feet << " I:" << inches << endl;
    }
};

int main()
{
    Distance D1(11, 10), D2;

    cout << "First Distance : "; D1.displayDistance();

    D2 = D1(10, 10, 10); // invoke operator()
    cout << "Second Distance :";
```

```
D2.displayDistance();

return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
First Distance : F: 11 I:10
Second Distance : F: 30 I:120
```

Subscripting[] Operator Overloading

The subscript operator [] is normally used to access array elements. This operator can be overloaded to enhance the existing functionality of C++ arrays.

Following example explains how a subscript operator [] can be overloaded.

```
#include <iostream>
using namespace std;
const int SIZE = 10;

class safearray
{
private:
    int arr[SIZE];
public:
    safearray()
    {
        register int i;
        for(i = 0; i < SIZE; i++)
        {
            arr[i] = i;
        }
    }
    int &operator[](int i)
    {
        if( i > SIZE )
        {
            cout << "Index out of bounds"
                <<endl; // return first element.
            return arr[0];
        }
        return arr[i];
    }
};

int main()
{
    safearray A;

    cout << "Value of A[2] : " << A[2] <<endl;
    cout << "Value of A[5] : " << A[5]<<endl;
    cout << "Value of A[12] : " << A[12]<<endl;

    return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Value of A[2] : 2
```

```
Value of A[5] : 5
Index out of bounds
Value of A[12] : 0
```

Class member access Operator -> Overloading

The class member access operator (->) can be overloaded but it is bit trickier. It is defined to give a class type a "pointer-like" behavior. The operator -> must be a member function. If used, its return type must be a pointer or an object of a class to which you can apply.

The operator-> is used often in conjunction with the pointer-dereference operator * to implement "smart pointers." These pointers are objects that behave like normal pointers except they perform other tasks when you access an object through them, such as automatic object deletion either when the pointer is destroyed, or the pointer is used to point to another object.

The dereferencing operator-> can be defined as a unary postfix operator. That is, given a class:

```
class Ptr{
    //...
    X * operator->();
};
```

Objects of class **Ptr** can be used to access members of class **X** in a very similar manner to the way pointers are used. For example:

```
void f(Ptr p )
{
    p->m = 10 ; // (p.operator->())->m = 10
}
```

The statement `p->m` is interpreted as `(p.operator->())->m`. Using the same concept, following example explain how a class access operator -> can be overloaded.

```
#include <iostream>
#include <vector>
using namespace std;

// Consider an actual
class. class Obj {
    static int i, j;
public:
    void f() const { cout << i++ << endl; }
    void g() const { cout << j++ << endl; }
};

// Static member definitions:
int Obj::i = 10;
int Obj::j = 12;

// Implement a container for the above class
class ObjContainer {
    vector<Obj*>
a; public:
    void add(Obj* obj)
    {
        a.push_back(obj); // call vector's standard method.
    }
    friend class SmartPointer;
};
```

```

// implement smart pointer to access member of Obj class.
class SmartPointer {
    ObjContainer oc;
    int index;
public:
    SmartPointer(ObjContainer& objc)
    {
        oc = objc;
        index = 0;
    }
    // Return value indicates end of list:
    bool operator++() // Prefix version
    {
        if(index >= oc.a.size()) return
        false; if(oc.a[++index] == 0) return
        false; return true;
    }
    bool operator++(int) // Postfix version
    {
        return operator++();
    }
    // overload operator->
    Obj* operator->() const
    {
        if(!oc.a[index])
        {
            cout << "Zero value";
            return (Obj*)0;
        }
        return oc.a[index];
    }
};

int main() {
    const int sz =
    10; Obj o[sz];
    ObjContainer oc;
    for(int i = 0; i < sz; i++)
    {
        oc.add(&o[i]);
    }
    SmartPointer sp(oc); // Create an iterator
    do {
        sp->f(); // smart pointer
        call sp->g();
    } while(sp++);
    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

10
12
11
13

Polymorphism

The word **polymorphism** means having many forms. Typically, polymorphism occurs when there is a hierarchy of classes and they are related by inheritance.

C++ polymorphism means that a call to a member function will cause a different function to be executed depending on the type of object that invokes the function.

Consider the following example where a base class has been derived by other two classes:

```
#include <iostream>
using namespace std;

class Shape {
protected:
    int width, height;
public:
    Shape( int a=0, int b=0)
    {
        width = a;
        height = b;
    }
    int area()
    {
        cout << "Parent class area : "
        <<endl; return 0;
    }
};

class Rectangle: public Shape{
public:
    Rectangle( int a=0, int b=0)
    {
        Shape(a, b);
    }
    int area ()
    {
        cout << "Rectangle class area : "
        <<endl; return (width * height);
    }
};

class Triangle: public Shape{
public:
    Triangle( int a=0, int b=0)
```

```

    {
        Shape(a, b);
    }
    int area ()
    {
        cout << "Rectangle class area : "
        <<endl; return (width * height / 2);
    }
};
// Main function for the program
int main( )
{
    Shape *shape;
    Rectangle rec(10,7);
    Triangle tri(10,5);

    // store the address of
    Rectangle shape = &rec;
    // call rectangle area.
    shape->area();

    // store the address of Triangle
    shape = &tri;
    // call triangle area.
    shape->area();

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Parent class area
Parent class area

```

The reason for the incorrect output is that the call of the function area() is being set once by the compiler as the version defined in the base class. This is called **static resolution** of the function call, or **static linkage** - the function call is fixed before the program is executed. This is also sometimes called **early binding** because the area() function is set during the compilation of the program.

But now, let's make a slight modification in our program and precede the declaration of area() in the Shape class with the keyword **virtual** so that it looks like this:

```

class Shape {
protected:
    int width, height;
public:
    Shape( int a=0, int b=0)
    {
        width = a;
        height = b;
    }
    virtual int area()
    {
        cout << "Parent class area : "
        <<endl; return 0;
    }
};

```

After this slight modification, when the previous example code is compiled and executed, it produces the following result:

```
Rectangle class area  
Triangle class area
```

This time, the compiler looks at the contents of the pointer instead of its type. Hence, since addresses of objects of tri and rec classes are stored in *shape, the respective area() function is called.

As you can see, each of the child classes has a separate implementation for the function area(). This is how **polymorphism** is generally used. You have different classes with a function of the same name, and even the same parameters, but with different implementations.

Virtual Function:

A **virtual** function is a function in a base class that is declared using the keyword **virtual**. Defining in a base class a virtual function, with another version in a derived class, signals to the compiler that we don't want static linkage for this function.

What we do want is the selection of the function to be called at any given point in the program to be based on the kind of object for which it is called. This sort of operation is referred to as **dynamic linkage**, or **late binding**.

Pure Virtual Functions:

It's possible that you'd want to include a virtual function in a base class so that it may be redefined in a derived class to suit the objects of that class, but that there is no meaningful definition you could give for the function in the base class.

We can change the virtual function area() in the base class to the following:

```
class Shape {  
    protected:  
        int width, height;  
    public:  
        Shape( int a=0, int b=0)  
        {  
            width = a;  
            height = b;  
        }  
        // pure virtual function  
        virtual int area() = 0;  
};
```

The = 0 tells the compiler that the function has no body and above virtual function will be called **pure virtual function**.

Data Abstraction

Data abstraction refers to, providing only essential information to the outside world and hiding their background details, i.e., to represent the needed information in program without presenting the details.

Data abstraction is a programming (and design) technique that relies on the separation of interface and implementation.

Let's take one real life example of a TV, which you can turn on and off, change the channel, adjust the volume, and add external components such as speakers, VCRs, and DVD players, BUT you do not know its internal details, that is, you do not know how it receives signals over the air or through a cable, how it translates them, and finally displays them on the screen.

Thus, we can say a television clearly separates its internal implementation from its external interface and you can play with its interfaces like the power button, channel changer, and volume control without having zero knowledge of its internals.

Now, if we talk in terms of C++ Programming, C++ classes provides great level of **data abstraction**. They provide sufficient public methods to the outside world to play with the functionality of the object and to manipulate object data, i.e., state without actually knowing how class has been implemented internally.

For example, your program can make a call to the **sort()** function without knowing what algorithm the function actually uses to sort the given values. In fact, the underlying implementation of the sorting functionality could change between releases of the library, and as long as the interface stays the same, your function call will still work.

In C++, we use **classes** to define our own abstract data types (ADT). You can use the **cout** object of class **ostream** to stream data to standard output like this:

```
#include <iostream>
using namespace std;

int main( )
{
    cout << "Hello C++" <<endl;
    return 0;
}
```

Here, you don't need to understand how **cout** displays the text on the user's screen. You need to only know the public interface and the underlying implementation of **cout** is free to change.

Access Labels Enforce Abstraction:

In C++, we use access labels to define the abstract interface to the class. A class may contain zero or more access labels:

- Members defined with a public label are accessible to all parts of the program. The data-abstraction view of a type is defined by its public members.
- Members defined with a private label are not accessible to code that uses the class. The private sections hide the implementation from code that uses the type.

There are no restrictions on how often an access label may appear. Each access label specifies the access level of the succeeding member definitions. The specified access level remains in effect until the next access label is encountered or the closing right brace of the class body is seen.

Benefits of Data Abstraction:

Data abstraction provides two important advantages:

- Class internals are protected from inadvertent user-level errors, which might corrupt the state of the object.
- The class implementation may evolve over time in response to changing requirements or bug reports without requiring change in user-level code.

By defining data members only in the private section of the class, the class author is free to make changes in the data. If the implementation changes, only the class code needs to be examined to see what affect the change may have. If data are public, then any function that directly accesses the data members of the old representation might be broken.

Data Abstraction Example:

Any C++ program where you implement a class with public and private members is an example of data abstraction. Consider the following example:

```
#include <iostream>
using namespace std;

class Adder{
public:
    // constructor
    Adder(int i = 0)
    {
        total = i;
    }
    // interface to outside world
    void addNum(int number)
    {
        total += number;
    }
    // interface to outside world
    int getTotal()
    {
        return total;
    };
private:
    // hidden data from outside world
```

```
        int total;
    };
    int main( )
    {
        Adder a;

        a.addNum(10);
        a.addNum(20);
        a.addNum(30);

        cout << "Total " << a.getTotal()
        <<endl; return 0;
    }
```

When the above code is compiled and executed, it produces the following result:

```
Total 60
```

Above class adds numbers together, and returns the sum. The public members **addNum** and **getTotal** are the interfaces to the outside world and a user needs to know them to use the class. The private member **total** is something that the user doesn't need to know about, but is needed for the class to operate properly.

Designing Strategy:

Abstraction separates code into interface and implementation. So while designing your component, you must keep interface independent of the implementation so that if you change underlying implementation then interface would remain intact.

In this case whatever programs are using these interfaces, they would not be impacted and would just need a recompilation with the latest implementation.

Data Encapsulation

A

ll C++ programs are composed of the following two fundamental elements:

- **Program statements (code):** This is the part of a program that performs actions and they are called functions.
- **Program data:** The data is the information of the program which affected by the program functions.

Encapsulation is an Object Oriented Programming concept that binds together the data and functions that manipulate the data, and that keeps both safe from outside interference and misuse. Data encapsulation led to the important OOP concept of **data hiding**.

Data encapsulation is a mechanism of bundling the data, and the functions that use them and **data abstraction** is a mechanism of exposing only the interfaces and hiding the implementation details from the user.

C++ supports the properties of encapsulation and data hiding through the creation of user-defined types, called **classes**. We already have studied that a class can contain **private**, **protected** and **public** members. By default, all items defined in a class are private. For example:

```
class Box
{
    public:
        double getVolume(void)
        {
            return length * breadth * height;
        }
    private:
        double length;        // Length of a box
        double breadth;       // Breadth of a box
        double height;        // Height of a box
};
```

The variables length, breadth, and height are **private**. This means that they can be accessed only by other members of the Box class, and not by any other part of your program. This is one way encapsulation is achieved.

To make parts of a class **public** (i.e., accessible to other parts of your program), you must declare them after the **public** keyword. All variables or functions defined after the public specifier are accessible by all other functions in your program.

Making one class a friend of another exposes the implementation details and reduces encapsulation. The ideal is to keep as many of the details of each class hidden from all other classes as possible.

Data Encapsulation Example:

Any C++ program where you implement a class with public and private members is an example of data encapsulation and data abstraction. Consider the following example:

```
#include <iostream>
using namespace std;

class Adder{
public:
    // constructor
    Adder(int i = 0)
    {
        total = i;
    }
    // interface to outside world
    void addNum(int number)
    {
        total += number;
    }
    // interface to outside world
    int getTotal()
    {
        return total;
    };
private:
    // hidden data from outside world
    int total;
};

int main( )
{
    Adder a;

    a.addNum(10);
    a.addNum(20);
    a.addNum(30);

    cout << "Total " << a.getTotal()
    << endl; return 0;
}
```

When the above code is compiled and executed, it produces the following result:

```
Total 60
```

Above class adds numbers together, and returns the sum. The public members **addNum** and **getTotal** are the interfaces to the outside world and a user needs to know them to use the class. The private member **total** is something that is hidden from the outside world, but is needed for the class to operate properly.

Designing Strategy:

Most of us have learned through bitter experience to make class members private by default unless we really need to expose them. That's just good **encapsulation**.

This wisdom is applied most frequently to data members, but it applies equally to all members, including virtual functions.

Interfaces

An interface describes the behavior or capabilities of a C++ class without committing to a particular implementation of that class.

The C++ interfaces are implemented using **abstract classes** and these abstract classes should not be confused with data abstraction which is a concept of keeping implementation details separate from associated data.

A class is made abstract by declaring at least one of its functions as **pure virtual** function. A pure virtual function is specified by placing "= 0" in its declaration as follows:

```
class Box
{
public:
    // pure virtual function
    virtual double getVolume() = 0;
private:
    double length;        // Length of a box
    double breadth;       // Breadth of a box
    double height;        // Height of a box
};
```

The purpose of an **abstract class** (often referred to as an ABC) is to provide an appropriate base class from which other classes can inherit. Abstract classes cannot be used to instantiate objects and serves only as an **interface**. Attempting to instantiate an object of an abstract class causes a compilation error.

Thus, if a subclass of an ABC needs to be instantiated, it has to implement each of the virtual functions, which means that it supports the interface declared by the ABC. Failure to override a pure virtual function in a derived class, then attempting to instantiate objects of that class, is a compilation error.

Classes that can be used to instantiate objects are called **concrete classes**.

Abstract Class Example:

Consider the following example where parent class provides an interface to the base class to implement a function called **getArea()**:

```
#include <iostream>

using namespace std;

// Base class
```

```

class Shape
{
public:
    // pure virtual function providing interface
    framework. virtual int getArea() = 0;
    void setWidth(int w)
    {
        width = w;
    }
    void setHeight(int h)
    {
        height = h;
    }
protected: int
    width; int
    height;
};

// Derived classes
class Rectangle: public Shape
{
public:
    int getArea()
    {
        return (width * height);
    }
};
class Triangle: public Shape
{
public:
    int getArea()
    {
        return (width * height)/2;
    }
};

int main(void)
{
    Rectangle Rect;
    Triangle Tri;

    Rect.setWidth(5);
    Rect.setHeight(7);
    // Print the area of the object.
    cout << "Total Rectangle area: " << Rect.getArea() << endl;

    Tri.setWidth(5);
    Tri.setHeight(7);
    // Print the area of the object.
    cout << "Total Triangle area: " << Tri.getArea() << endl;

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Total Rectangle area: 35
Total Triangle area: 17

```

You can see how an abstract class defined an interface in terms of `getArea()` and two other classes implemented same function but with different algorithm to calculate the area specific to the shape.

Designing Strategy:

An object-oriented system might use an abstract base class to provide a common and standardized interface appropriate for all the external applications. Then, through inheritance from that abstract base class, derived classes are formed that all operate similarly.

The capabilities (i.e., the public functions) offered by the external applications are provided as pure virtual functions in the abstract base class. The implementations of these pure virtual functions are provided in the derived classes that correspond to the specific types of the application.

This architecture also allows new applications to be added to a system easily, even after the system has been defined.

Files and Streams

So far, we have been using the **iostream** standard library, which provides **cin** and **cout** methods for reading from standard input and writing to standard output respectively.

This tutorial will teach you how to read and write from a file. This requires another standard C++ library called **fstream**, which defines three new data types:

Data Type	Description
Ofstream	This data type represents the output file stream and is used to create files and to write information to files.
Ifstream	This data type represents the input file stream and is used to read information from files.
Fstream	This data type represents the file stream generally, and has the capabilities of both ofstream and ifstream which means it can create files, write information to files, and read information from files.

To perform file processing in C++, header files `<iostream>` and `<fstream>` must be included in your C++ source file.

Opening a File:

A file must be opened before you can read from it or write to it. Either the **ofstream** or **fstream** object may be used to open a file for writing and **ifstream** object is used to open a file for reading purpose only.

Following is the standard syntax for `open()` function, which is a member of **fstream**, **ifstream**, and **ofstream** objects.

```
void open(const char *filename, ios::openmode mode);
```

Here, the first argument specifies the name and location of the file to be opened and the second argument of the **open()** member function defines the mode in which the file should be opened.

Mode Flag	Description
ios::app	Append mode. All output to that file to be appended to the end.
ios::ate	Open a file for output and move the read/write control to the end of the file.
ios::in	Open a file for reading.

ios::out	Open a file for writing.
ios::trunc	If the file already exists, its contents will be truncated before opening the file.

You can combine two or more of these values by **OR**ing them together. For example if you want to open a file in write mode and want to truncate it in case it already exists, following will be the syntax:

```
ofstream outfile;
outfile.open("file.dat", ios::out | ios::trunc );
```

Similar way, you can open a file for reading and writing purpose as follows:

```
fstream afile;
afile.open("file.dat", ios::out | ios::in );
```

Closing a File

When a C++ program terminates, it automatically closes flushes all the streams, release all the allocated memory and close all the opened files. But it is always a good practice that a programmer should close all the opened files before program termination.

Following is the standard syntax for close() function, which is a member of fstream, ifstream, and ofstream objects.

```
void close();
```

Writing to a File:

While doing C++ programming, you write information to a file from your program using the stream insertion operator (<<) just as you use that operator to output information to the screen. The only difference is that you use an **ofstream** or **fstream** object instead of the **cout** object.

Reading from a File:

You read information from a file into your program using the stream extraction operator (<<) just as you use that operator to input information from the keyboard. The only difference is that you use an **ifstream** or **fstream** object instead of the **cin** object.

Read & Write Example:

Following is the C++ program which opens a file in reading and writing mode. After writing information inputted by the user to a file named afile.dat, the program reads information from the file and outputs it onto the screen:

```
#include <fstream>
#include <iostream>
using namespace std;

int main ()
{
    char data[100];

    // open a file in write mode.
    ofstream outfile;
    outfile.open("afile.dat");

    cout << "Writing to the file" <<
    endl; cout << "Enter your name: ";
    cin.getline(data, 100);
```

```

// write inputted data into the file.
outfile << data << endl;

cout << "Enter your age: ";
cin >> data;
cin.ignore();

// again write inputted data into the
file. outfile << data << endl;

// close the opened file.
outfile.close();

// open a file in read
mode. ifstream infile;
infile.open("afile.dat");

cout << "Reading from the file" <<
endl; infile >> data;

// write the data at the screen.
cout << data << endl;

// again read the data from the file and display it.
infile >> data;
cout << data << endl;

// close the opened file.
infile.close();

return 0;
}

```

When the above code is compiled and executed, it produces following sample input and output:

```

$./a.out
Writing to the file
Enter your name:
Zara Enter your age:
9 Reading from the
file Zara
9

```

Above examples make use of additional functions from cin object, like `getline()` function to read the line from outside and `ignore()` function to ignore the extra characters left by previous read statement.

File Position Pointers:

Both **istream** and **ostream** provide member functions for repositioning the file-position pointer. These member functions are **seekg** ("seek get") for istream and **seekp** ("seek put") for ostream.

The argument to `seekg` and `seekp` normally is a long integer. A second argument can be specified to indicate the seek direction. The seek direction can be **ios::beg** (the default) for positioning relative to the beginning of a stream, **ios::cur** for positioning relative to the current position in a stream or **ios::end** for positioning relative to the end of a stream.

The file-position pointer is an integer value that specifies the location in the file as a number of bytes from the file's starting location. Some examples of positioning the "get" file-position pointer are:

```
// position to the nth byte of fileObject (assumes  
ios::beg) fileObject.seekg( n );  
  
// position n bytes forward in fileObject  
fileObject.seekg( n, ios::cur );  
  
// position n bytes back from end of fileObject  
fileObject.seekg( n, ios::end );  
  
// position at end of fileObject  
fileObject.seekg( 0, ios::end );
```

Exception Handling

An exception is a problem that arises during the execution of a program. A C++ exception is a response to an exceptional circumstance that arises while a program is running, such as an attempt to divide by zero.

Exceptions provide a way to transfer control from one part of a program to another. C++ exception handling is built upon three keywords: **try**, **catch**, and **throw**.

- **throw**: A program throws an exception when a problem shows up. This is done using a **throw** keyword.
- **catch**: A program catches an exception with an exception handler at the place in a program where you want to handle the problem. The **catch** keyword indicates the catching of an exception.
- **try**: A **try** block identifies a block of code for which particular exceptions will be activated. It's followed by one or more catch blocks.

Assuming a block will raise an exception, a method catches an exception using a combination of the **try** and **catch** keywords. A try/catch block is placed around the code that might generate an exception. Code within a try/catch block is referred to as protected code, and the syntax for using try/catch looks like the following:

```
try
{
    // protected code
} catch( ExceptionName e1 )
{
    // catch block
} catch( ExceptionName e2 )
{
    // catch block
} catch( ExceptionName eN )
{
    // catch block
}
```

You can list down multiple **catch** statements to catch different type of exceptions in case your **try** block raises more than one exception in different situations.

Throwing Exceptions:

Exceptions can be thrown anywhere within a code block using **throw** statements. The operand of the throw statements determines a type for the exception and can be any expression and the type of the result of the expression determines the type of exception thrown.

Following is an example of throwing an exception when dividing by zero condition occurs:

```
double division(int a, int b)
{
    if( b == 0 )
    {
        throw "Division by zero condition!";
    }
    return (a/b);
}
```

Catching Exceptions:

The **catch** block following the **try** block catches any exception. You can specify what type of exception you want to catch and this is determined by the exception declaration that appears in parentheses following the keyword catch.

```
try
{
    // protected code
} catch( ExceptionName e )
{
    // code to handle ExceptionName exception
}
```

Above code will catch an exception of **ExceptionName** type. If you want to specify that a catch block should handle any type of exception that is thrown in a try block, you must put an ellipsis, ..., between the parentheses enclosing the exception declaration as follows:

```
try
{
    // protected
code } catch(...)
{
    // code to handle any exception
}
```

The following is an example, which throws a division by zero exception and we catch it in catch block.

```
#include <iostream>
using namespace std;

double division(int a, int b)
{
    if( b == 0 )
    {
        throw "Division by zero condition!";
    }
    return (a/b);
}

int main ()
{
    int x = 50;
    int y = 0;
    double z = 0;

    try {
        z = division(x, y);
        cout << z << endl;
    } catch (const char* msg) {
        cerr << msg << endl;
    }
}
```

```

    }

    return 0;
}

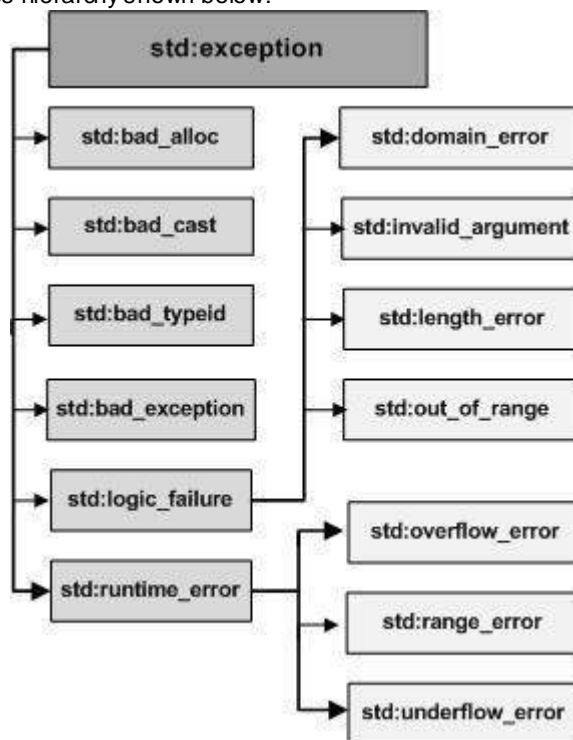

```

Because we are raising an exception of type **const char***, so while catching this exception, we have to use **const char*** in catch block. If we compile and run above code, this would produce the following result:

```
Division by zero condition!
```

C++ Standard Exceptions:

C++ provides a list of standard exceptions defined in **<exception>** which we can use in our programs. These are arranged in a parent-child class hierarchy shown below:

Here is the small description of each exception mentioned in the above hierarchy:

Exception	Description
std::exception	An exception and parent class of all the standard C++ exceptions.
std::bad_alloc	This can be thrown by new .
std::bad_cast	This can be thrown by dynamic_cast .
std::bad_exception	This is useful device to handle unexpected exceptions in a C++ program
std::bad_typeid	This can be thrown by typeid .
std::logic_error	An exception that theoretically can be detected by reading the code.
std::domain_error	This is an exception thrown when a mathematically invalid domain is used

std::invalid_argument	This is thrown due to invalid arguments.
std::length_error	This is thrown when a too big std::string is created
std::out_of_range	This can be thrown by the at method from for example a std::vector and std::bitset<>::operator[]().
std::runtime_error	An exception that theoretically can not be detected by reading the code.
std::overflow_error	This is thrown if a mathematical overflow occurs.
std::range_error	This is occurred when you try to store a value which is out of range.
std::underflow_error	This is thrown if a mathematical underflow occurs.

Define New Exceptions:

You can define your own exceptions by inheriting and overriding **exception** class functionality. Following is the example, which shows how you can use std::exception class to implement your own exception in standard way:

```
#include <iostream>
#include <exception>
using namespace std;

struct MyException : public exception
{
    const char * what () const throw ()
    {
        return "C++ Exception";
    }
};

int main()
{
    try
    {
        throw MyException();
    }
    catch(MyException& e)
    {
        std::cout << "MyException caught" <<
        std::endl; std::cout << e.what() << std::endl;
    }
    catch(std::exception& e)
    {
        //Other errors
    }
}
```

This would produce the following result:

```
MyException caught
C++ Exception
```

Here, **what()** is a public method provided by exception class and it has been overridden by all the child exception classes. This returns the cause of an exception.

Dynamic Memory

A good understanding of how dynamic memory really works in C++ is essential to becoming a good C++ programmer. Memory in your C++ program is divided into two parts:

- **The stack:** All variables declared inside the function will take up memory from the stack.
- **The heap:** This is unused memory of the program and can be used to allocate the memory dynamically when program runs.

Many times, you are not aware in advance how much memory you will need to store particular information in a defined variable and the size of required memory can be determined at run time.

You can allocate memory at run time within the heap for the variable of a given type using a special operator in C++ which returns the address of the space allocated. This operator is called **new** operator.

If you are not in need of dynamically allocated memory anymore, you can use **delete** operator, which de-allocates memory previously allocated by new operator.

The new and delete operators:

There is following generic syntax to use **new** operator to allocate memory dynamically for any data-type.

```
new data-type;
```

Here, **data-type** could be any built-in data type including an array or any user defined data types include class or structure. Let us start with built-in data types. For example we can define a pointer to type double and then request that the memory be allocated at execution time. We can do this using the **new** operator with the following statements:

```
double* pvalue = NULL; // Pointer initialized with null
pvalue = new double;    // Request memory for the variable
```

The memory may not have been allocated successfully, if the free store had been used up. So it is good practice to check if new operator is returning NULL pointer and take appropriate action as below:

```
double* pvalue = NULL;
if( !(pvalue = new double ) )
{
    cout << "Error: out of memory." << endl;
    exit(1);
}
```

The **malloc()** function from C, still exists in C++, but it is recommended to avoid using malloc() function. The main advantage of new over malloc() is that new doesn't just allocate memory, it constructs objects which is prime purpose of C++.

At any point, when you feel a variable that has been dynamically allocated is not anymore required, you can free up the memory that it occupies in the free store with the delete operator as follows:

```
delete pvalue;           // Release memory pointed to by pvalue
```

Let us put above concepts and form the following example to show how new and delete work:

```
#include <iostream>
using namespace std;

int main ()
{
    double* pvalue = NULL; // Pointer initialized with null
    pvalue = new double; // Request memory for the variable

    *pvalue = 29494.99; // Store value at allocated address
    cout << "Value of pvalue : " << *pvalue << endl;

    delete pvalue;        // free up the memory.

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
Value of pvalue : 29495
```

Dynamic Memory Allocation for Arrays:

Consider you want to allocate memory for an array of characters, i.e., string of 20 characters. Using the same syntax what we have used above we can allocate memory dynamically as shown below.

```
char* pvalue = NULL; // Pointer initialized with null
pvalue = new char[20]; // Request memory for the variable
```

To remove the array that we have just created the statement would look like this:

```
delete [] pvalue;        // Delete array pointed to by pvalue
```

Following the similar generic syntax of new operator, you can allocat for a multi-dimensional array as follows:

```
double** pvalue = NULL; // Pointer initialized with null
pvalue = new double [3][4]; // Allocate memory for a 3x4 array
```

However, the syntax to release the memory for multi-dimensional array will still remain same as above:

```
delete [] pvalue;        // Delete array pointed to by pvalue
```

Dynamic Memory Allocation for Objects:

Objects are no different from simple data types. For example, consider the following code where we are going to use an array of objects to clarify the concept:

```
#include <iostream>
using namespace std;
```

```

class Box
{
    public:
        Box() {
            cout << "Constructor called!" <<endl;
        }
        ~Box() {
            cout << "Destructor called!" <<endl;
        }
};

int main( )
{
    Box* myBoxArray = new Box[4];

    delete [] myBoxArray; // Delete array

    return 0;
}

```

If you were to allocate an array of four Box objects, the Simple constructor would be called four times and similarly while deleting these objects, destructor will also be called same number of times.

If we compile and run above code, this would produce the following result:

```

Constructor called!
Constructor called!
Constructor called!
Constructor called!
Destructor called!
Destructor called!
Destructor called!
Destructor called!

```

Namespaces

Consider a situation, when we have two persons with the same name, Zara, in the same class. Whenever we need to differentiate them definitely we would have to use some additional information along with their name, like either the area if they live in different area or their mother or father name, etc.

Same situation can arise in your C++ applications. For example, you might be writing some code that has a function called xyz() and there is another library available which is also having same function xyz(). Now the compiler has no way of knowing which version of xyz() function you are referring to within your code.

A **namespace** is designed to overcome this difficulty and is used as additional information to differentiate similar functions, classes, variables etc. with the same name available in different libraries. Using namespace, you can define the context in which names are defined. In essence, a namespace defines a scope.

Defining a Namespace:

A namespace definition begins with the keyword **namespace** followed by the namespace name as follows:

```
namespace namespace_name
{ // code declarations
}
```

To call the namespace-enabled version of either function or variable, prepend the namespace name as follows:

```
name::code; // code could be variable or function.
```

Let us see how namespace scope the entities including variable and functions:

```
#include <iostream>
using namespace std;

// first name space
namespace first_space{
    void func(){
        cout << "Inside first_space" << endl;
    }
}

// second name space
namespace second_space{
    void func(){
        cout << "Inside second_space" << endl;
    }
}
```

```

}
int main ()
{

    // Calls function from first name
    space. first_space::func();

    // Calls function from second name space.
    second_space::func();

    return 0;
}

```

If we compile and run above code, this would produce the following result:

```

Inside first_space
Inside second_space

```

The using directive:

You can also avoid prepending of namespaces with the **using namespace** directive. This directive tells the compiler that the subsequent code is making use of names in the specified namespace. The namespace is thus implied for the following code:

```

#include <iostream>
using namespace std;

// first name space
namespace first_space{
    void func(){
        cout << "Inside first_space" << endl;
    }
}

// second name space
namespace second_space{
    void func(){
        cout << "Inside second_space" << endl;
    }
}

using namespace
first_space; int main ()
{

    // This calls function from first name
    space. func();

    return 0;
}

```

If we compile and run above code, this would produce the following result:

```

Inside first_space

```

The using directive can also be used to refer to a particular item within a namespace. For example, if the only part of the std namespace that you intend to use is cout, you can refer to it as follows:

```

using std::cout;

```

Subsequent code can refer to `cout` without prepending the namespace, but other items in the **std** namespace will still need to be explicit as follows:

```
#include <iostream>
using std::cout;

int main ()
{
    cout << "std::endl is used with std!" << std::endl;

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
std::endl is used with std!
```

Names introduced in a **using** directive obey normal scope rules. The name is visible from the point of the **using** directive to the end of the scope in which the directive is found. Entities with the same name defined in an outer scope are hidden.

Discontiguous Namespaces:

A namespace can be defined in several parts and so a namespace is made up of the sum of its separately defined parts. The separate parts of a namespace can be spread over multiple files.

So, if one part of the namespace requires a name defined in another file, that name must still be declared. Writing a following namespace definition either defines a new namespace or adds new elements to an existing one:

```
namespace namespace_name
{ // code declarations
}
```

Nested Namespaces:

Namespaces can be nested where you can define one namespace inside another name space as follows:

```
namespace namespace_name1 { //
    code declarations namespace
    namespace_name2 {
        // code declarations
    }
}
```

You can access members of nested namespace by using resolution operators as follows:

```
// to access members of namespace_name2
using namespace namespace_name1::namespace_name2;

// to access members of namespace_name1
using namespace namespace_name1;
```

In the above statements, if you are using `namespace_name1`, then it will make elements of `namespace_name2` available in the scope as follows:

```
#include <iostream>
using namespace std;
```

```
// first name space
namespace first_space{
    void func(){
        cout << "Inside first_space" << endl;
    }
    // second name space
    namespace second_space{
        void func(){
            cout << "Inside second_space" << endl;
        }
    }
}

using namespace first_space::second_space;
int main ()
{

    // This calls function from first name
    space. func();

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
Inside second_space
```

Templates

Templates are the foundation of generic programming, which involves writing code in a way that is independent of any particular type.

A template is a blueprint or formula for creating a generic class or a function. The library containers like iterators and algorithms are examples of generic programming and have been developed using template concept.

There is a single definition of each container, such as **vector**, but we can define many different kinds of vectors for example, **vector <int>** or **vector <string>**.

You can use templates to define functions as well as classes, let us see how do they work:

Function Template:

The general form of a template function definition is shown here:

```
template <class type> ret-type func-name(parameter list)
{
    // body of function
}
```

Here, type is a placeholder name for a data type used by the function. This name can be used within the function definition.

The following is the example of a function template that returns the maximum of two values:

```
#include <iostream>
#include <string>

using namespace std;

template <typename T>
inline T const& Max (T const& a, T const& b)
{
    return a < b ? b:a;
}

int main ()
{
    int i = 39;
```

```

    int j = 20;
    cout << "Max(i, j): " << Max(i, j) << endl;

    double f1 = 13.5;
    double f2 = 20.7;
    cout << "Max(f1, f2): " << Max(f1, f2) << endl;

    string s1 = "Hello";
    string s2 = "World";
    cout << "Max(s1, s2): " << Max(s1, s2) << endl;

    return 0;
}

```

If we compile and run above code, this would produce the following result:

```

Max(i, j): 39
Max(f1, f2): 20.7
Max(s1, s2): World

```

Class Template:

Just as we can define function templates, we can also define class templates. The general form of a generic class declaration is shown here:

```

template <class type> class class-name {
.
.
.
}

```

Here, **type** is the placeholder type name, which will be specified when a class is instantiated. You can define more than one generic data type by using a comma-separated list.

Following is the example to define class Stack<> and implement generic methods to push and pop the elements from the stack:

```

#include <iostream>
#include <vector>
#include <cstdlib>
#include <string>
#include <stdexcept>

using namespace std;

template <class T>
class Stack {
private:
    vector<T> elems;    // elements

public:
    void push(T const&); // push element
    void pop();          // pop element
    T top() const;       // return top element
    bool empty() const { // return true if empty.
        return elems.empty();
    }
};

```

```

template <class T>
void Stack<T>::push (T const& elem)
{
    // append copy of passed
    element elems.push_back(elem);
}

template <class T>
void Stack<T>::pop ()
{
    if (elems.empty()) {
        throw out_of_range("Stack<>::pop(): empty stack");
    }

    // remove last
    element elems.pop_back();
}

template <class T>
T Stack<T>::top () const
{
    if (elems.empty()) {
        throw out_of_range("Stack<>::top(): empty stack");
    }

    // return copy of last
    element return elems.back();
}

int main()
{
    try {
        Stack<int>          intStack; // stack of ints
        Stack<string> stringStack;    // stack of strings

        // manipulate int stack
        intStack.push(7);
        cout << intStack.top() << endl;

        // manipulate string stack
        stringStack.push("hello");
        cout << stringStack.top() << std::endl;
        stringStack.pop();
        stringStack.pop();
    }
    catch (exception const& ex) {
        cerr << "Exception: " << ex.what() << endl;
        return -1;
    }
}

```

If we compile and run above code, this would produce the following result:

```

7
hello
Exception: Stack<>::pop(): empty stack

```

Preprocessor

The preprocessors are the directives which give instruction to the compiler to preprocess the information before actual compilation starts.

All preprocessor directives begin with #, and only white-space characters may appear before a preprocessor directive on a line. Preprocessor directives are not C++ statements, so they do not end in a semicolon (;).

You already have seen a **#include** directive in all the examples. This macro is used to include a header file into the source file.

There are number of preprocessor directives supported by C++ like #include, #define, #if, #else, #line, etc. Let us see important directives:

The #define Preprocessor:

The #define preprocessor directive creates symbolic constants. The symbolic constant is called a **macro** and the general form of the directive is:

```
#define macro-name replacement-text
```

When this line appears in a file, all subsequent occurrences of macro in that file will be replaced by replacement-text before the program is compiled. For example:

```
#include <iostream>
using namespace std;

#define PI 3.14159

int main ()
{
    cout << "Value of PI :" << PI << endl;

    return 0;
}
```

Now, let us do the preprocessing of this code to see the result, assume we have source code file, so let us compile it with -E option and redirect the result to test.p. Now, if you will check test.p, it will have lots of information, and at the bottom, you will find the value replaced as follows:

```
$gcc -E test.cpp > test.p

...
int main ()
{

    cout << "Value of PI :" << 3.14159 << endl;

    return 0;
}
```

Function-Like Macros:

You can use `#define` to define a macro which will take argument as follows:

```
#include <iostream>
using namespace std;

#define MIN(a,b) (((a)<(b)) ? a : b)

int main ()
{
    int i, j;
    i = 100;
    j = 30;
    cout << "The minimum is " << MIN(i, j) << endl;

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
The minimum is 30
```

Conditional Compilation:

There are several directives, which can use to compile selectively portions of your program's source code. This process is called conditional compilation.

The conditional preprocessor construct is much like the if selection structure. Consider the following preprocessor code:

```
#ifndef NULL
#define NULL 0
#endif
```

You can compile a program for debugging purpose and can debugging turn on or off using a single macro as follows:

```
#ifdef DEBUG
    cerr << "Variable x = " << x << endl;
#endif
```

causes the **cerr** statement to be compiled in the program if the symbolic constant **DEBUG** has been defined before directive `#ifdef DEBUG`. You can use `#if 0` statement to comment out a portion of the program as follows:

```
#if 0
    code prevented from compiling
```

```
#endif
```

Let us try the following example:

```
#include <iostream>
using namespace
std; #define DEBUG

#define MIN(a,b) (((a)<(b)) ? a : b)

int main ()
{
    int i, j;
    i = 100;
    j = 30;
    #ifdef DEBUG
        cerr << "Trace: Inside main function" <<
endl; #endif

    #if 0
        /* This is commented part */
        cout << MKSTR(HELLO C++) <<
endl; #endif

        cout << "The minimum is " << MIN(i, j) << endl;

    #ifdef DEBUG
        cerr << "Trace: Coming out of main function" <<
endl; #endif
        return 0;
}
```

If we compile and run above code, this would produce the following result:

```
Trace: Inside main function
The minimum is 30
Trace: Coming out of main function
```

The # and ## Operators:

The # and ## preprocessor operators are available in C++ and ANSI/ISO C. The # operator causes a replacement-text token to be converted to a string surrounded by quotes.

Consider the following macro definition:

```
#include <iostream>
using namespace std;

#define MKSTR( x ) #x

int main ()
{
    cout << MKSTR(HELLO C++) << endl;

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
HELLO C++
```

Let us see how it worked. It is simple to understand that the C++ preprocessor turns the line:

```
cout << MKSTR(HELLO C++) << endl;
```

into the following line:

```
cout << "HELLO C++" << endl;
```

The ## operator is used to concatenate two tokens. Here is an example:

```
#define CONCAT( x, y ) x ## y
```

When CONCAT appears in the program, its arguments are concatenated and used to replace the macro. For example, CONCAT(HELLO, C++) is replaced by "HELLO C++" in the program as follows.

```
#include <iostream>
using namespace std;

#define concat(a, b) a ## b
int main()
{
    int xy = 100;

    cout << concat(x, y);
    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
100
```

Let us see how it worked. It is simple to understand that the C++ preprocessor transforms:

```
cout << concat(x, y);
```

into the following line:

```
cout << xy;
```

Predefined C++ Macros:

C++ provides a number of predefined macros mentioned below:

Macro	Description
__LINE__	This contain the current line number of the program when it is being compiled.
__FILE__	This contain the current file name of the program when it is being compiled.
__DATE__	This contains a string of the form month/day/year that is the date of the translation of the source file into object code.
__TIME__	This contains a string of the form hour:minute:second that is the time at which the program was compiled.

Let us see an example for all the above macros:

```
#include <iostream>
using namespace std;

int main ()
{
    cout << "Value of __LINE__ : " << __LINE__ << endl;
    cout << "Value of __FILE__ : " << __FILE__ << endl;
    cout << "Value of __DATE__ : " << __DATE__ << endl;
    cout << "Value of __TIME__ : " << __TIME__ << endl;

    return 0;
}
```

If we compile and run above code, this would produce the following result:

```
Value of __LINE__ : 6
Value of __FILE__ : test.cpp
Value of __DATE__ : Feb 28 2011
Value of __TIME__ : 18:52:48
```

Signal Handling

Signals are the interrupts delivered to a process by the operating system which can terminate a program prematurely. You can generate interrupts by pressing Ctrl+C on a UNIX, LINUX, Mac OS X or Windows system.

There are signals which can not be caught by the program but there is a following list of signals which you can catch in your program and can take appropriate actions based on the signal. These signals are defined in C++ header file <csignal>.

Signal	Description
SIGABRT	Abnormal termination of the program, such as a call to abort
SIGFPE	An erroneous arithmetic operation, such as a divide by zero or an operation resulting in overflow.
SIGILL	Detection of an illegal instruction
SIGINT	Receipt of an interactive attention signal.
SIGSEGV	An invalid access to storage.
SIGTERM	A termination request sent to the program.

The signal() function:

C++ signal-handling library provides function **signal** to trap unexpected events. Following is the syntax of the signal() function:

```
void (*signal (int sig, void (*func)(int)))(int);
```

Keeping it simple, this function receives two arguments: first argument as an integer which represents signal number and second argument as a pointer to the signal-handling function.

Let us write a simple C++ program where we will catch SIGINT signal using signal() function. Whatever signal you want to catch in your program, you must register that signal using **signal** function and associate it with a signal handler. Examine the following example:

```
#include <iostream>
#include <csignal>
```

```

using namespace std;

void signalHandler( int signum )
{
    cout << "Interrupt signal ( " << signum << " ) received.\n";

    // cleanup and close up stuff here
    // terminate program

    exit(signum);
}

int main ()
{
    // register signal SIGINT and signal
    handler signal(SIGINT, signalHandler);

    while(1){
        cout << "Going to sleep...." << endl;
        sleep(1);
    }

    return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

Going to sleep....
Going to sleep....
Going to sleep....

```

Now, press Ctrl+c to interrupt the program and you will see that your program will catch the signal and would come out by printing something as follows:

```

Going to sleep....
Going to sleep....
Going to sleep....
Interrupt signal (2) received.

```

The raise() function:

You can generate signals by function **raise()**, which takes an integer signal number as an argument and has the following syntax.

```

int raise (signal sig);

```

Here, **sig** is the signal number to send any of the signals: SIGINT, SIGABRT, SIGFPE, SIGILL, SIGSEGV, SIGTERM, SIGHUP. Following is the example where we raise a signal internally using raise() function as follows:

```

#include <iostream>
#include <csignal>

using namespace std;

void signalHandler( int signum )
{
    cout << "Interrupt signal ( " << signum << " ) received.\n";
}

```

```

        // cleanup and close up stuff here
        // terminate program

        exit(signum);
    }

    int main ()
    {
        int i = 0;
        // register signal SIGINT and signal
        handler signal(SIGINT, signalHandler);

        while(++i){
            cout << "Going to sleep...." << endl;
            if( i == 3 ){
                raise( SIGINT);
            }
            sleep(1);
        }

        return 0;
    }

```

When the above code is compiled and executed, it produces the following result and would come out automatically:

```

Going to sleep....
Going to sleep....
Going to sleep....
Interrupt signal (2) received.

```

Multithreading

Multithreading is a specialized form of multitasking and a multitasking is the feature that allows your

computer to run two or more programs concurrently. In general, there are two types of multitasking: process-based and thread-based.

Process-based multitasking handles the concurrent execution of programs. Thread-based multitasking deals with the concurrent execution of pieces of the same program.

A multithreaded program contains two or more parts that can run concurrently. Each part of such a program is called a thread, and each thread defines a separate path of execution.

C++ does not contain any built-in support for multithreaded applications. Instead, it relies entirely upon the operating system to provide this feature.

This tutorial assumes that you are working on Linux OS and we are going to write multi-threaded C++ program using POSIX. POSIX Threads, or Pthreads provides API which are available on many Unix-like POSIX systems such as FreeBSD, NetBSD, GNU/Linux, Mac OS X and Solaris.

Creating Threads:

There is following routine which we use to create a POSIX thread:

```
#include <pthread.h>
pthread_create (thread, attr, start_routine, arg)
```

Here **pthread_create** creates a new thread and makes it executable. This routine can be called any number of times from anywhere within your code. Here is the description of the parameters:

Parameter	Description
Thread	An opaque, unique identifier for the new thread returned by the subroutine.
Attr	An opaque attribute object that may be used to set thread attributes. You can specify a thread attributes object, or NULL for the default values.
start_routine	The C++ routine that the thread will execute once it is created.
Arg	A single argument that may be passed to start_routine. It must be passed by reference as a pointer cast of type void. NULL may be used if no argument is to be

passed.

The maximum number of threads that may be created by a process is implementation dependent. Once created, threads are peers, and may create other threads. There is no implied hierarchy or dependency between threads.

Terminating Threads:

There is following routine which we use to terminate a POSIX thread:

```
#include <pthread.h>
pthread_exit (status)
```

Here, **pthread_exit** is used to explicitly exit a thread. Typically, the `pthread_exit()` routine is called after a thread has completed its work and is no longer required to exist.

If `main()` finishes before the threads it has created, and exits with `pthread_exit()`, the other threads will continue to execute. Otherwise, they will be automatically terminated when `main()` finishes.

Example:

This simple example code creates 5 threads with the `pthread_create()` routine. Each thread prints a "Hello World!" message, and then terminates with a call to `pthread_exit()`.

```
#include <iostream>
#include <pthread.h>

using namespace std;

#define NUM_THREADS      5

void *PrintHello(void *threadid)
{
    long tid;
    tid = (long)threadid;
    cout << "Hello World! Thread ID, " << tid <<
    endl; pthread_exit(NULL);
}

int main ()
{
    pthread_t threads[NUM_THREADS];
    int rc;
    int i;
    for( i=0; i < NUM_THREADS; i++ ){
        cout << "main() : creating thread, " << i <<
        endl; rc = pthread_create(&threads[i], NULL,
                                PrintHello, (void *)i);

        if (rc){
            cout << "Error:unable to create thread," << rc <<
            endl; exit(-1);
        }
    }
    pthread_exit(NULL);
}
```

Compile the following program using `-lpthread` library as follows:

```
$gcc test.cpp -lpthread
```

Now, execute your program, which should generate results something as follows:

```
main() : creating thread, 0
main() : creating thread, 1
main() : creating thread, 2
main() : creating thread, 3
main() : creating thread, 4
Hello World! Thread ID, 0
Hello World! Thread ID, 1
Hello World! Thread ID, 2
Hello World! Thread ID, 3
Hello World! Thread ID, 4
```

Passing Arguments to Threads:

This example shows how to pass multiple arguments via a structure. You can pass any data type in a thread callback because it points to void as explained in the following example:

```
#include <iostream>
#include <pthread.h>

using namespace std;

#define NUM_THREADS      5

struct thread_data{
    int    thread_id;
    char *message;
};

void *PrintHello(void *threadarg)
{
    struct thread_data *my_data;

    my_data = (struct thread_data *) threadarg;

    cout << "Thread ID : " << my_data->thread_id ; cout
    << " Message : " << my_data->message << endl;

    pthread_exit(NULL);
}

int main ()
{
    pthread_t threads[NUM_THREADS];
    struct thread_data
    td[NUM_THREADS]; int rc;
    int i;

    for( i=0; i < NUM_THREADS; i++ ){
        cout <<"main() : creating thread, " << i << endl;
        td[i].thread_id = i;
        td[i].message = "This is message";
        rc = pthread_create(&threads[i], NULL,
                           PrintHello, (void *)&td[i]);
        if (rc){
            cout << "Error:unable to create thread," << rc <<
            endl; exit(-1);
        }
    }
}
```

```

    }
}
pthread_exit(NULL);
}

```

When the above code is compiled and executed, it produces the following result:

```

main() : creating thread, 0
main() : creating thread, 1
main() : creating thread, 2
main() : creating thread, 3
main() : creating thread, 4
Thread ID : 3 Message : This is message
Thread ID : 2 Message : This is message
Thread ID : 0 Message : This is message
Thread ID : 1 Message : This is message
Thread ID : 4 Message : This is message

```

Joining and Detaching Threads:

There are following two routines which we can use to join or detach threads:

```

pthread_join (threadid, status)
pthread_detach (threadid)

```

The `pthread_join()` subroutine blocks the calling thread until the specified `threadid` thread terminates. When a thread is created, one of its attributes defines whether it is joinable or detached. Only threads that are created as joinable can be joined. If a thread is created as detached, it can never be joined.

This example demonstrates how to wait for thread completions by using the Pthread join routine.

```

#include <iostream>
#include <pthread.h>

using namespace std;

#define NUM_THREADS      5

void *wait(void *t)
{
    int i;
    long tid;

    tid = (long)t;

    sleep(1);
    cout << "Sleeping in thread " << endl;
    cout << "Thread with id : " << tid << " ...exiting " << endl;
    pthread_exit(NULL);
}

int main ()
{
    int rc;
    int i;
    pthread_t threads[NUM_THREADS];
    pthread_attr_t attr;
    void *status;

```

```

// Initialize and set thread joinable pthread_attr_init(&attr);
pthread_attr_setdetachstate(&attr, PTHREAD_CREATE_JOINABLE);

for( i=0; i < NUM_THREADS; i++ ){
    cout << "main() : creating thread, " << i << endl;
    rc = pthread_create(&threads[i], NULL, wait, (void *)i );
    if (rc){
        cout << "Error:unable to create thread," << rc <<
        endl; exit(-1);
    }
}

// free attribute and wait for the other
threads pthread_attr_destroy(&attr);
for( i=0; i < NUM_THREADS; i++ ){
    rc = pthread_join(threads[i], &status);
    if (rc){
        cout << "Error:unable to join," << rc <<
        endl; exit(-1);
    }
    cout << "Main: completed thread id : " << i ;
    cout << "  exiting with status : " << (int)status << endl;
}

cout << "Main: program exiting." << endl;
pthread_exit(NULL);
}

```

When the above code is compiled and executed, it produces the following result:

```

main() : creating thread, 0
main() : creating thread, 1
main() : creating thread, 2
main() : creating thread, 3
main() : creating thread, 4
Sleeping in thread
Thread with id : 0 .... exiting
Sleeping in thread
Thread with id : 1 .... exiting
Sleeping in thread
Thread with id : 2 .... exiting
Sleeping in thread
Thread with id : 3 .... exiting
Sleeping in thread
Thread with id : 4 .... exiting
Main: completed thread id :0  exiting with status :0
Main: completed thread id :1  exiting with status :0
Main: completed thread id :2  exiting with status :0
Main: completed thread id :3  exiting with status :0
Main: completed thread id :4  exiting with status :0
Main: program exiting.

```

Web Programming

What is CGI?

It includes the following:

- The Common Gateway Interface, or CGI, is a set of standards that define how information is exchanged between the web server and a custom script.
- The CGI specs are currently maintained by the NCSA and NCSA defines CGI is as follows:
- The Common Gateway Interface, or CGI, is a standard for external gateway programs to interface with information servers such as HTTP servers.
- The current version is CGI/1.1 and CGI/1.2 is under progress.

Web Browsing

To understand the concept of CGI, let's see what happens when we click a hyperlink to browse a particular web page or URL.

- Your browser contacts the HTTP web server and demand for the URL ie. filename.
- Web Server will parse the URL and will look for the filename. If it finds requested file then web server sends that file back to the browser otherwise sends an error message indicating that you have requested a wrong file.
- Web browser takes response from web server and displays either the received file or error message based on the received response.

However, it is possible to set up the HTTP server in such a way that whenever a file in a certain directory is requested, that file is not sent back; instead it is executed as a program, and produced output from the program is sent back to your browser to display.

The Common Gateway Interface (CGI) is a standard protocol for enabling applications (called CGI programs or CGI scripts) to interact with Web servers and with clients. These CGI programs can be written in Python, PERL, Shell, C or C++ etc.

CGI Architecture Diagram

The following simple program shows a simple architecture of CGI:

Web Server Configuration

Before you proceed with CGI Programming, make sure that your Web Server supports CGI and it is configured to handle CGI Programs. All the CGI Programs to be executed by the HTTP server are kept in a pre-configured directory. This directory is called CGI directory and by convention it is named as `/var/www/cgi-bin`. By convention CGI files will have extension as `.cgi`, though they are C++ executable.

By default, Apache Web Server is configured to run CGI programs in `/var/www/cgi-bin`. If you want to specify any other directory to run your CGI scripts, you can modify the following section in the `httpd.conf` file:

```
<Directory "/var/www/cgi-bin">
    AllowOverride None
    Options ExecCGI
    Order allow,deny
    Allow from all
</Directory>

<Directory "/var/www/cgi-bin"> Options All
</Directory>
```

Here, I assumed that you have Web Server up and running successfully and you are able to run any other CGI program like Perl or Shell, etc.

First CGI Program

Consider the following C++ Program content:

```
#include <iostream>
using namespace std;

int main ()
{
    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>Hello World - First CGI Program</title>\n";
    cout << "</head>\n";
}
```

```

cout << "<body>\n";
cout << "<h2>Hello World! This is my first CGI
program</h2>\n"; cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

Compile above code and name the executable as `cplusplus.cgi`. This file is being kept in `/var/www/cgi-bin` directory and it has following content. Before running your CGI program make sure you have change mode of file using **`chmod 755 cplusplus.cgi`** UNIX command to make file executable. Now if you click [cplusplus.cgi](#) then this produces following output:

Hello World! This is my first CGI program

Above C++ program is a simple program which is writing its output on STDOUT file ie. screen. There is one important and extra feature available which is first line to be printed **`Content-type: text/html\r\n\r\n`**. This line is sent back to the browser and specify the content type to be displayed on the browser screen. Now you must have understood basic concept of CGI and you can write many complicated CGI programs using Python. A C++ CGI program can interact with any other external system, such as RDBMS, to exchange information.

HTTP Header

The line **`Content-type: text/html\r\n\r\n`** is part of HTTP header, which is sent to the browser to understand the content. All the HTTP header will be in the following form

```

HTTP Field Name: Field Content

For Example
Content-type: text/html\r\n\r\n

```

There are few other important HTTP headers, which you will use frequently in your CGI Programming.

Header	Description
Content-type:	A MIME string defining the format of the file being returned. Example is <code>Content-type: text/html</code>
Expires: Date	The date the information becomes invalid. This should be used by the browser to decide when a page needs to be refreshed. A valid date string should be in the format <code>01 Jan 1998 12:00:00 GMT</code> .
Location: URL	The URL that should be returned instead of the URL requested. You can use this field to redirect a request to any file.
Last-modified: Date	The date of last modification of the resource.
Content-length: N	The length, in bytes, of the data being returned. The browser uses this value to report the estimated download time for a file.
Set-Cookie: String	Set the cookie passed through the <i>string</i>

CGI Environment Variables

All the CGI program will have access to the following environment variables. These variables play an important role while writing any CGI program.

Variable Name	Description
---------------	-------------

CONTENT_TYPE	The data type of the content. Used when the client is sending attached content to the server. For example file upload etc.
CONTENT_LENGTH	The length of the query information. It's available only for POST requests
HTTP_COOKIE	Return the set cookies in the form of key & value pair.
HTTP_USER_AGENT	The User-Agent request-header field contains information about the user agent originating the request. Its name of the web browser.
PATH_INFO	The path for the CGI script.
QUERY_STRING	The URL-encoded information that is sent with GET method request.
REMOTE_ADDR	The IP address of the remote host making the request. This can be useful for logging or for authentication purpose.
REMOTE_HOST	The fully qualified name of the host making the request. If this information is not available then REMOTE_ADDR can be used to get IR address.
REQUEST_METHOD	The method used to make the request. The most common methods are GET and POST.
SCRIPT_FILENAME	The full path to the CGI script.
SCRIPT_NAME	The name of the CGI script.
SERVER_NAME	The server's hostname or IP Address
SERVER_SOFTWARE	The name and version of the software the server is running.

Here is small CGI program to list out all the CGI variables. Click this link to see the result [Get Environment](#)

```
#include <iostream>
#include <stdlib.h>
using namespace std;

const string ENV[ 24 ] = {
    "COMSPEC", "DOCUMENT_ROOT", "GATEWAY_INTERFACE",
    "HTTP_ACCEPT", "HTTP_ACCEPT_ENCODING",
    "HTTP_ACCEPT_LANGUAGE", "HTTP_CONNECTION",
    "HTTP_HOST", "HTTP_USER_AGENT", "PATH",
    "QUERY_STRING", "REMOTE_ADDR", "REMOTE_PORT",
    "REQUEST_METHOD", "REQUEST_URI", "SCRIPT_FILENAME",
    "SCRIPT_NAME", "SERVER_ADDR", "SERVER_ADMIN",
    "SERVER_NAME", "SERVER_PORT", "SERVER_PROTOCOL",
    "SERVER_SIGNATURE", "SERVER_SOFTWARE" };

int main ()
{
    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>CGI Envrionment\n";
    cout << "</head>\n";
    cout << "<body>\n";
    cout << "<table border = \"0\" cellspacing = \"2\">";

    for ( int i = 0; i < 24; i++ )
    {
```

```

cout << "<tr><td>" << ENV[ i ] << "</td><td>";
// attempt to retrieve value of environment variable
char *value = getenv( ENV[ i ].c_str() );
if ( value != 0 ){
    cout << value;
}else{
    cout << "Environment variable does not exist.";
}
cout << "</td></tr>\n";
}
cout << "</table><\n";
cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

C++ CGI Library

For real examples, you would need to do many operations by your CGI program. There is a CGI library written for C++ program which you can download from <ftp://ftp.gnu.org/gnu/cgicc/> and following the following steps to install the library:

```

$tar xzf cgicc-X.X.X.tar.gz
$cd cgicc-X.X.X/
$./configure --prefix=/usr
$make
$make install

```

You can check related documentation available at [C++ CGI Lib Documentation](#).

GET and POST Methods

You must have come across many situations when you need to pass some information from your browser to web server and ultimately to your CGI Program. Most frequently browser uses two methods to pass this information to web server. These methods are GET Method and POST Method.

Passing Information using GET method:

The GET method sends the encoded user information appended to the page request. The page and the encoded information are separated by the ? character as follows:

```
http://www.test.com/cgi-bin/cpp.cgi?key1=value1&key2=value2
```

The GET method is the default method to pass information from browser to web server and it produces a long string that appears in your browser's Location:box. Never use the GET method if you have password or other sensitive information to pass to the server. The GET method has size limitation and you can pass upto 1024 characters in a request string.

When using GET method, information is passed using QUERY_STRING http header and will be accessible in your CGI Program through QUERY_STRING environment variable

You can pass information by simply concatenating key and value pairs alongwith any URL or you can use HTML <FORM> tags to pass information using GET method.

Simple URL Example : Get Method

Here is a simple URL which will pass two values to hello_get.py program using GET method.

/cgi-bin/cpp_get.cgi?first_name=ZARA&last_name=ALI

Below is program to generate **cpp_get.cgi** CGI program to handle input given by web browser. We are going to use C++ CGI library which makes it very easy to access passed information:

```
#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc formData;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>Using GET and POST Methods</title>\n";
    cout << "</head>\n";
    cout << "<body>\n";

    form_iterator fi = formData.getElement("first_name");
    if( !fi->isEmpty() && fi != (*formData).end()) {
        cout << "First name: " << **fi << endl;
    }else{
        cout << "No text entered for first name" << endl;
    }
    cout << "<br/>\n";
    fi = formData.getElement("last_name");
    if( !fi->isEmpty() && fi != (*formData).end()) {
        cout << "Last name: " << **fi << endl;
    }else{
        cout << "No text entered for last name" << endl;
    }
    cout << "<br/>\n";

    cout << "</body>\n";
    cout << "</html>\n";

    return 0;
}
```

Now, compile the above program as follows:

```
$g++ -o cpp_get.cgi cpp_get.cpp -lcgicc
```

Generate **cpp_get.cgi** and put it in your CGI directory and try to access using following link:

/cgi-bin/cpp_get.cgi?first_name=ZARA&last_name=ALI

This would generate following result:

```
First name: ZARA
Last name: ALI
```

Simple FORM Example: GET Method

Here is a simple example which passes two values using HTML FORM and submit button. We are going to use same CGI script `cpp_get.cgi` to handle this input.

```
<form action="/cgi-bin/cpp_get.cgi" method="get">
First Name: <input type="text" name="first_name"> <br />

Last Name: <input type="text" name="last_name" />
<input type="submit" value="Submit" />
</form>
```

Here is the actual output of the above form, You enter First and Last Name and then click submit button to see the result.

A screenshot of a web browser showing a simple HTML form. It has two text input fields. The first field is labeled "First Name:" and the second is labeled "Last Name:". To the right of the "Last Name:" field is a "Submit" button. The form is styled with a light gray background and a simple border.

Passing Information using POST method:

A generally more reliable method of passing information to a CGI program is the POST method. This packages the information in exactly the same way as GET methods, but instead of sending it as a text string after a ? in the URL it sends it as a separate message. This message comes into the CGI script in the form of the standard input.

The same `cpp_get.cgi` program will handle POST method as well. Let us take same example as above, which passes two values using HTML FORM and submit button but this time with POST method as follows:

```
<form action="/cgi-bin/cpp_get.cgi" method="post">
First Name: <input type="text" name="first_name"><br
/> Last Name: <input type="text" name="last_name" />

<input type="submit" value="Submit"
/> </form>
```

Here is the actual output of the above form, You enter First and Last Name and then click submit button to see the result.

A screenshot of a web browser showing a simple HTML form, identical to the one in the GET method example. It has two text input fields labeled "First Name:" and "Last Name:", and a "Submit" button to the right of the "Last Name:" field. The form is styled with a light gray background and a simple border.

Passing Checkbox Data to CGI Program

Checkboxes are used when more than one option is required to be selected.

Here is example HTML code for a form with two checkboxes

```
<form action="/cgi-bin/cpp_checkbox.cgi"
      method="POST"
      target="_blank">
<input type="checkbox" name="maths" value="on" /> Maths
<input type="checkbox" name="physics" value="on" /> Physics
<input type="submit" value="Select Subject" />
</form>
```

The result of this code is the following form

The screenshot shows a web browser window displaying the rendered HTML form. It contains two checkboxes, one for 'Maths' and one for 'Physics', both of which are currently unchecked. To the right of these checkboxes is a button labeled 'Select Subject'.

Below is C++ program, which will generate cpp_checkbox.cgi script to handle input given by web browser through checkbox button.

```
#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc formData;
    bool maths_flag, physics_flag;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>Checkbox Data to\n";
    cout << "CGI</title>\n"; cout << "</head>\n";
    cout << "<body>\n";

    maths_flag = formData.queryCheckbox("maths");
    if( maths_flag ) {
        cout << "Maths Flag: ON " << endl;
    }else{
        cout << "Maths Flag: OFF " << endl;
    }
    cout << "<br/>\n";

    physics_flag = formData.queryCheckbox("physics");
    if( physics_flag ) {
        cout << "Physics Flag: ON " << endl;
    }
}
```

```

    }else{
        cout << "Physics Flag: OFF " << endl;
    }
    cout << "<br/>\n";
    cout << "</body>\n";
    cout << "</html>\n";

    return 0;
}

```

Passing Radio Button Data to CGI Program

Radio Buttons are used when only one option is required to be selected.

Here is example HTML code for a form with two radio button:

```

<form action="/cgi-bin/cpp_radiobutton.cgi"
        method="post"
        target="_blank">
<input type="radio" name="subject" value="maths"
        checked="checked"/> Maths
<input type="radio" name="subject" value="physics" />
Physics <input type="submit" value="Select Subject" />
</form>

```

The result of this code is the following form

Below is C++ program, which will generate cpp_radiobutton.cgi script to handle input given by web browser through radio buttons.

```

#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc formData;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>Radio Button Data to CGI</title>\n";
    cout << "</head>\n";
    cout << "<body>\n";

    form_iterator fi = formData.getElement("subject");

```

```

    if( !fi->isEmpty() && fi != (*formData).end()) {
        cout << "Radio box selected: " << **fi << endl;
    }

    cout << "<br/>\n";
    cout << "</body>\n";
    cout << "</html>\n";

    return 0;
}

```

Passing Text Area Data to CGI Program

TEXTAREA element is used when multiline text has to be passed to the CGI Program.

Here is example HTML code for a form with a TEXTAREA box:

```

<form action="/cgi-bin/cpp_textarea.cgi"
      method="post"
      target="_blank">
<textarea name="textcontent" cols="40"
rows="4"> Type your text here...
</textarea>
<input type="submit" value="Submit"
/> </form>

```

The result of this code is the following form

The screenshot shows a web browser window with a form. The form contains a text area with the placeholder text "Type your text here..." and a "Submit" button. The text area is empty, and the button is visible to the right of the text area.

Below is C++ program, which will generate cpp_textarea.cgi script to handle input given by web browser through text area.

```

#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc formData;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>Text Area Data to CGI</title>\n";
}

```

```

cout << "</head>\n";
cout << "<body>\n";

form_iterator fi = formData.getElement("textcontent");
if( !fi->isEmpty() && fi != (*formData).end()) {
    cout << "Text Content: " << **fi << endl;
}else{
    cout << "No text entered" << endl;
}

cout << "<br/>\n";
cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

Passing Drop Down Box Data to CGI Program

Drop Down Box is used when we have many options available but only one or two will be selected. Here is example HTML code for a form with one drop down box

```

<form action="/cgi-bin/cpp_dropdown.cgi" method="post"
      target="_blank">
<select name="dropdown">
<option value="Maths"
selected>Maths</option> <option
value="Physics">Physics</option> </select>
<input type="submit" value="Submit"/>
</form>

```

The result of this code is the following form

Below is C++ program, which will generate cpp_dropdown.cgi script to handle input given by web browser through drop down box.

```

#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc formData;

    cout << "Content-type:text/html\r\n\r\n";

```

```

cout << "<html>\n";
cout << "<head>\n";
cout << "<title>Drop Down Box Data to\n";
cout << "</title>\n"; cout << "</head>\n";
cout << "<body>\n";

form_iterator fi = formData.getElement("dropdown");
if( !fi->isEmpty() && fi != (*formData).end()) {
    cout << "Value Selected: " << **fi << endl;
}

cout << "<br/>\n";
cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

Using Cookies in CGI

HTTP protocol is a stateless protocol. But for a commercial website it is required to maintain session information among different pages. For example one user registration ends after completing many pages. But how to maintain user's session information across all the web pages.

In many situations, using cookies is the most efficient method of remembering and tracking preferences, purchases, commissions, and other information required for better visitor experience or site statistics.

How It Works

Your server sends some data to the visitor's browser in the form of a cookie. The browser may accept the cookie. If it does, it is stored as a plain text record on the visitor's hard drive. Now, when the visitor arrives at another page on your site, the cookie is available for retrieval. Once retrieved, your server knows/remembers what was stored.

Cookies are a plain text data record of 5 variable-length fields:

- **Expires** : The date the cookie will expire. If this is blank, the cookie will expire when the visitor quits the browser.
- **Domain** : The domain name of your site.
- **Path** : The path to the directory or web page that set the cookie. This may be blank if you want to retrieve the cookie from any directory or page.
- **Secure** : If this field contains the word "secure" then the cookie may only be retrieved with a secure server. If this field is blank, no such restriction exists.
- **Name=Value** : Cookies are set and retrieved in the form of key and value pairs.

Setting up Cookies

This is very easy to send cookies to browser. These cookies will be sent along with HTTP Header before to Content-type field. Assuming you want to set UserID and Password as cookies. So cookies setting will be done as follows

```

#include <iostream>
using namespace std;

int main ()
{
    cout << "Set-Cookie:UserID=XYZ;\r\n" ;
}

```

```

cout << "Set-Cookie:Password=XYZ123;\r\n";
cout << "Set-Cookie:Domain=www.tutorialspoint.com;\r\n";
cout << "Set-Cookie:Path=/perl;\n";
cout << "Content-type:text/html\r\n\r\n";

cout << "<html>\n";
cout << "<head>\n";
cout << "<title>Cookies in CGI</title>\n";
cout << "</head>\n";
cout << "<body>\n";

cout << "Setting cookies" << endl;

cout << "<br/>\n";
cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

From this example, you must have understood how to set cookies. We use **Set-Cookie** HTTP header to set cookies.

Here, it is optional to set cookies attributes like Expires, Domain, and Path. It is notable that cookies are set before sending magic line "**Content-type:text/html\r\n\r\n**".

Compile above program to produce setcookies.cgi and try to set cookies using following link. It will set four cookies at your computer:

</cgi-bin/setcookies.cgi>

Retrieving Cookies

This is very easy to retrieve all the set cookies. Cookies are stored in CGI environment variable HTTP_COOKIE and they will have following form.

```
key1=value1;key2=value2;key3=value3....
```

Here is an example of how to retrieving cookies.

```

#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h> #include
<cgicc/HTTPHTMLHeader.h> #include
<cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc cgi;
    const_cookie_iterator cci;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";

```

```

cout << "<head>\n";
cout << "<title>Cookies in CGI</title>\n";
cout << "</head>\n";
cout << "<body>\n";
cout << "<table border = \"0\" cellspacing = \"2\">";

// get environment variables
const CgiEnvironment& env = cgi.getEnvironment();

for( cci = env.getCookieList().begin();
    cci != env.getCookieList().end();
    ++cci )
{
    cout << "<tr><td>" << cci->getName() << "</td><td>";
    cout << cci->getValue();
    cout << "</td></tr>\n";
}
cout << "</table>\n";

cout << "<br/>\n";
cout << "</body>\n";
cout << "</html>\n";

return 0;
}

```

Now, compile above program to produce getcookies.cgi and try to get a list of all the cookies available at your computer:

[/cgi-bin/getcookies.cgi](#)

This will produce a list of all the four cookies set in previous section and all other cookies set at your computer:

```

UserID XYZ
Password XYZ123
Domain www.tutorialspoint.com
Path /perl

```

File Upload Example:

To upload a file the HTML form must have the enctype attribute set to **multipart/form-data**. The input tag with the file type will create a "Browse" button.

```

<html>
<body>
    <form enctype="multipart/form-data"
        action="/cgi-bin/cpp_uploadfile.cgi"
        method="post">
        <p>File: <input type="file" name="userfile"
        /></p> <p><input type="submit" value="Upload"
        /></p> </form>
    </body>
</html>

```

The result of this code is the following form:

File:

Upload

Note: Above example has been disabled intentionally to save people uploading files on our server. But you can try above code with your server.

Here is the script **cpp_uploadfile.cpp** to handle file upload:

```
#include <iostream>
#include <vector>
#include <string>
#include <stdio.h>
#include <stdlib.h>

#include <cgicc/CgiDefs.h>
#include <cgicc/Cgicc.h>
#include <cgicc/HTTPHTMLHeader.h>
#include <cgicc/HTMLClasses.h>

using namespace std;
using namespace cgicc;

int main ()
{
    Cgicc cgi;

    cout << "Content-type:text/html\r\n\r\n";
    cout << "<html>\n";
    cout << "<head>\n";
    cout << "<title>File Upload in CGI</title>\n";
    cout << "</head>\n";
    cout << "<body>\n";

    // get list of files to be uploaded
    const_file_iterator file = cgi.getFile("userfile");
    if(file != cgi.getFiles().end()) {
        // send data type at cout.
        cout << HTTPContentHeader(file->getDataType());
        // write content at cout. file-
        >writeToStream(cout);
    }
    cout << "<File uploaded successfully>\n";
    cout << "</body>\n";
    cout << "</html>\n";

    return 0;
}
```

The above example is writing content at **cout** stream but you can open your file stream and save the content of uploaded file in a file at desired location.

STL Tutorial

Hope you already understand the concept of C++ Template which we already have discussed in one of

the chapters. The C++ STL (Standard Template Library) is a powerful set of C++ template classes to provides general-purpose templated classes and functions that implement many popular and commonly used algorithms and data structures like vectors, lists, queues, and stacks.

At the core of the C++ Standard Template Library are following three well-structured components:

Component	Description
Containers	Containers are used to manage collections of objects of a certain kind. There are several different types of containers like deque, list, vector, map etc.
Algorithms	Algorithms act on containers. They provide the means by which you will perform initialization, sorting, searching, and transforming of the contents of containers.
Iterators	Iterators are used to step through the elements of collections of objects. These collections may be containers or subsets of containers.

We will discuss about all the three C++ STL components in next chapter while discussing C++ Standard Library. For now, keep in mind that all the three components have a rich set of pre-defined functions which help us in doing complicated tasks in very easy fashion.

Let us take the following program demonstrates the vector container (a C++ Standard Template) which is similar to an array with an exception that it automatically handles its own storage requirements in case it grows:

```
#include <iostream>
#include <vector>
using namespace std;

int main()
{
    // create a vector to store int
    vector<int> vec;
    int i;

    // display the original size of vec
    cout << "vector size = " << vec.size() << endl;
```

```

// push 5 values into the vector
for(i = 0; i < 5; i++){
    vec.push_back(i);
}

// display extended size of vec
cout << "extended vector size = " << vec.size() << endl;

// access 5 values from the vector
for(i = 0; i < 5; i++){
    cout << "value of vec [" << i << "] = " << vec[i] << endl;
}

// use iterator to access the values
vector<int>::iterator v =
vec.begin(); while( v != vec.end()) {
    cout << "value of v = " << *v << endl;
    v++;
}

return 0;
}

```

When the above code is compiled and executed, it produces the following result:

```

vector size = 0
extended vector size = 5
value of vec [0] = 0
value of vec [1] = 1
value of vec [2] = 2
value of vec [3] = 3
value of vec [4] = 4
value of v = 0
value of v = 1
value of v = 2
value of v = 3
value of v = 4

```

Here are following points to be noted related to various functions we used in the above example:

- The `push_back()` member function inserts value at the end of the vector, expanding its size as needed.
 - The `size()` function displays the size of the vector.
 - The function `begin()` returns an iterator to the start of the vector.
 - The function `end()` returns an iterator to the end of the vector.
-

Standard Library

The C++ Standard Library can be categorized into two parts:

- **The Standard Function Library:** This library consists of general-purpose, stand-alone functions that are not part of any class. The function library is inherited from C.
- **The Object Oriented Class Library:** This is a collection of classes and associated functions.

Standard C++ Library incorporates all the Standard C libraries also, with small additions and changes to support type safety.

The Standard Function Library:

The standard function library is divided into the following categories:

- I/O
- String and character handling
- Mathematical
- Time, date, and localization
- Dynamic allocation
- Miscellaneous
- Wide-character functions

The Object Oriented Class Library:

Standard C++ Object Oriented Library defines an extensive set of classes that provide support for a number of common activities, including I/O, strings, and numeric processing. This library includes the following:

- The Standard C++ I/O Classes
-

- The String Class
- The Numeric Classes
- The STL Container Classes
- The STL Algorithms
- The STL Function Objects
- The STL Iterators
- The STL Allocators
- The Localization library
- Exception Handling Classes
- Miscellaneous Support Library
